NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines®)

Central Nervous System Cancers

Version 3.2024 — September 30, 2024

NCCN.org

NCCN recognizes the importance of clinical trials and encourages participation when applicable and available.
Trials should be designed to maximize inclusiveness and broad representative enrollment.

NCCN Guidelines for Patients® available at www.nccn.org/patients

Updates in Version 3.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 2.2024 include:

[GLIO-A 2 of 9](#) and [GLIO-A 4 of 9](#)

Vorasidenib for *IDH1* or *IDH2* mutations added as an option for the following settings:

- Adjuvant treatment option after surgery/biopsy and treatment with RT and chemotherapy is not preferred, WHO grade 2, KPS ≥60
 - ▶ Oligodendroglioma (*category 1*), preferred
 - ▶ IDH-Mutant Astrocytoma (*category 1*), preferred
 - ▶ Footnote modified: Vorasidenib is a dual inhibitor of *IDH1* and *IDH2* mutations. In a phase 3 study of vorasidenib versus placebo (Mellinghoff IK, et al. N Engl J Med 2023;389:589-601) in patients with residual or recurrent grade 2 IDH-mutant glioma (after surgery and no prior treatment), vorasidenib improved median PFS (27.7 mo vs. 11.1 mo), compared to placebo. ~~Although the FDA approval process for vorasidenib is ongoing, eligible patients with newly diagnosed WHO grade 2 disease can obtain vorasidenib through an expanded access program (NCT05592743).~~ Also for footnote k on GLIO-2A, GLIO-4A.
- Adjuvant treatment option, KPS <60, WHO grade 2
 - ▶ Oligodendroglioma (*category 2A*), *Useful in Certain Circumstances*
- Adjuvant treatment option, KPS <60, WHO grade 2
 - ▶ IDH-Mutant Astrocytoma (*category 2A*), *Useful in Certain Circumstances*
- Recurrent or progressive disease after RT + chemotherapy WHO grade 2, KPS ≥60
 - ▶ Oligodendroglioma (*category 2A*), preferred
 - ▶ IDH-Mutant Astrocytoma (*category 2A*), preferred
- Recurrent or progressive disease, KPS ≥60
 - ▶ Oligodendroglioma, WHO grade 3 (*category 2B*), preferred
 - ▶ IDH-Mutant Astrocytoma, WHO grade 3 or WHO grade 4 (*category 2B*), preferred
- [GLIO-7](#)
 - ▶ Modified to include Recurrent or progressive disease....
- [BRAIN METS-A 1 of 4](#)
 - ▶ Modified to include TMB-H (≥10 mut/Mb) tumors

Updates in Version 2.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 1.2024 include:

[GLIO-A 1 of 9](#) and [GLIO-A 6 of 9](#)

- Recurrent or Progressive Disease
 - ▶ *NTRK* gene fusion-positive: Repotrectinib added as a category 2B, useful in certain circumstances recommendation

[GLIO-A 7 of 9](#) and [BRAIN METS-A 2 of 4](#)

- Reference added: Solomon BJ, Drilon A, Lin JJ, et al. Repotrectinib in patients (pts) with *NTRK* fusion-positive (*NTRK+*) advanced solid tumors, including NSCLC: Update from the phase I/II TRIDENT-1 trial. Annals of Oncology 2023;34:S755-S851.

[BRAIN METS-A 1 of 4](#)

- *NTRK* gene fusion-positive: Repotrectinib added as a category 2A, preferred recommendation

– Terminologies in all NCCN Guidelines are being actively modified to advance the goals of equity, inclusion, and representation.

Updates in Version 1.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 1.2023 include:

Global

- References have been updated throughout the guidelines.

GLIO-1

- Column 1, deleted: MRI suggestive of high-grade glioma
- Column 4, new: Circumscribed glioma/glioneuronal tumors
- Bullet 4, new: Dysembryoplastic neuroepithelial tumor (DNET)
- Bullet 6, new: Glioneuronal tumors for WHO grade 2
- Modified: If oligodendroglioma, grade 2, ~~isocitrate dehydrogenase~~ IDH mutant, 1p19q codeleted
- Modified: If IDH-mutant astrocytoma, grade 2 (GLIO-4); *for grades 3 and 4, see GLIO-5*
- Column 5, bullet 1, modified: PA, PXA, ganglioglioma/*neuroglioma/glioneuronal tumor*
- Sub-bullet 4, modified: Consider treatment with an mTOR inhibitor (eg, everolimus) *if symptomatic or growing*

Footnotes

- e, modified: Based on ~~Consider~~ a multidisciplinary review in for treatment planning, ~~especially~~ once pathology is available. (Also for GLIO-2A, GLIO-3, GLIO-4A, GLIO-5A, GLIO-6, GLIO-7, GLIO-8, EPEN-1, AMED-1, PSCT-1, LTD-1, MU-1, LEPT-1)
- f, new: WHO grade 1 tumors with concurrent *H3* and *BRAF* alterations may behave more aggressively.

GLIO-2

- WHO grades 2 and 3 have been separated and significant updates have been made to this page

GLIO-2A

- New: Vorasidenib is a dual inhibitor of *IDH1* and *IDH2* mutations. In a phase 3 study of vorasidenib versus placebo (Mellinghoff IK, et al. N Engl J Med 2023;389:589-601) in patients with residual or recurrent grade 2 IDH-mutant glioma (after surgery and no prior treatment) newly diagnosed WHO grade 2 or grade 3 gliomas, vorasidenib improved median PFS (27.7 mo vs. 11.1 mo), compared to placebo. Although the FDA approval process for vorasidenib is ongoing, eligible patients with newly diagnosed WHO grade 2 disease can obtain vorasidenib through an expanded access program (NCT05592743). (Also for GLIO-4A, GLIO-A, 3 of 9, GLIO-A. 5 of 9).

Deleted:

- i: Low-risk features: ≤40 y and gross total resection. (Also for GLIO-5A)
- j: High-risk features: >40 y or subtotal resection or open or stereotactic biopsy. Other high-risk factors that are sometimes taken into consideration are tumor size and neurologic deficits. (Also for GLIO-5A)
- l: In the event that other risk factors are considered and treatment is warranted, treat as high risk. There may also be rare circumstances in which treating a patient with fractionated external beam RT (EBRT) alone (category 2B) or systemic therapy alone (category 2B) may be considered. See Principles of Radiation Therapy for Brain and Spinal Cord (BRAIN-C) Oligodendroglioma Systemic Therapy Options (GLIO-A 2 of 8). (Also for GLIO-5A).
- p: The panel recommends that PCV be administered after RT (as per EORTC 26951) since the intensive PCV regimen given prior to RT (RTOG 9402) was not tolerated as well. (Also for GLIO-4A, GLIO-A, 5 of 9)
- q: Consider TMZ if tumor is O6-methylguanine-DNA methyltransferase (MGMT) promoter methylated. (Also for GLIO-3, GLIO-4A, GLIO-5A, GLIO-9, GLIO-10).

GLIO-3

- Page title, new: Adult Glioma: Oligodendroglioma (IDH-Mutant, 1p19q codeleted)
- New: WHO grade 3

Updates in Version 1.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 1.2023 include:

[GLIO-4](#)

- Adult Glioma: IDH-mutant astrocytoma
 - ▶ WHO grade 2 and WHO grades 3 and 4 have been separated.

[Adjuvant treatment](#)

- Good PS (KPS ≥60)
 - ▶ New: Residual or recurrent tumor after resection or biopsy and upfront treatment with RT and chemotherapy is not preferred
 - ▶ Bullet 1, new: IDH inhibitor
 - ▶ New: Initial treatment with RT and chemotherapy is preferred or tumor progression on an IDH inhibitor
- Poor PS (KPS <60)
 - ▶ New: IDH inhibitor

[GLIO-5](#)

- Column 1, new: "WHO grade 3/WHO grade 4," *IDH-Mutant Astrocytoma*
- Column 2: WHO grade 4
 - ▶ Deleted: Standard RT alone

[GLIO-5A](#)

- Deleted footnote k: Regular follow-up is essential for patients receiving observation alone after resection.
- Modified footnote p: Treatment of grade 4 disease is extrapolated from *interim analyses of data from the CATNON study*. Final results of CATNON are not yet available.

[GLIO-6](#)

- Page title, new: Adult Glioma: Recurrent or Progressive Circumscribed Glioma

[Treatment](#)

- Modified:
 - ▶ *Start systemic therapy*
 - ▶ Change *to a different systemic therapy regimen*
 - ▶ Consider reirradiation with highly focused RT ± systemic therapy in select cases ~~if new lesion outside target of prior standard RT or the recurrence is small and geometrically favorable~~
 - ▶ Consider observation for *gross totally resected tumors* ~~patients with low-risk disease~~

[Footnotes](#)

- Deleted t: If gross total resection is achieved in a patient with low-risk disease, consider further observation. (Also for GLIO-7)
- Deleted u: WHO Grade 1 or 2 have traditionally been considered low-grade gliomas. (Also for GLIO-7)

[GLIO-7](#)

- Page title, new: Adult Glioma: Recurrent Oligodendroglioma and Astrocytoma ~~Low-Grade~~ (WHO Grade 2)

[Footnotes](#)

- Deleted v: If radiographically the tumor appears to be a high-grade glioma, see GLIO-6.
- Deleted y: RT alone is not encouraged, but may be appropriate for select cases (eg, poor PS).

[GLIO-8](#)

- Deleted: Multidisciplinary input for treatment planning if feasible.

Updates in Version 1.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 1.2023 include:

[GLIO-9](#)

Adjuvant treatment

- Unmethylated
 - ▶ Modified: Standard RT + concurrent TMZ and "+" adjuvant TMZ....(Also for GLIO-10)

[GLIO-11](#)

- Page title, new: Adult Glioma: High Grade Glioma: Other
- Sub-title new: The treatment recommendations on this page are general high-grade glioma options. Tumor MGMT status and NGS should be performed to possibly expand therapeutic options.

Pathology

- New: PXA WHO grade 3, High grade astrocytoma with piloid features (HGAP)

Footnote

- ii, modified: Systemic therapy options for *the more common recurrent high grade gliomas* (glioblastoma, grade 3 oligodendroglioma, and grade 3 or 4 astrocytoma) also apply for ~~H3-mutated~~ to these other high-grade gliomas. See GLIO-A, 5 of 8.

[GLIO-12](#)

- Page title, new: Adult Glioma: Recurrent or Progressive Disease High-Grade (WHO Grades 3 & 4)
- Column 2, upper pathway, modified: Diffuse or *multifocal* ~~multiple~~

[GLIO-A \(1 of 9\)](#)

Adjuvant treatment/Useful in Certain Circumstances

- Modified: PA, *circumscribed* ganglioglioma/neuroglioma/glioneuronal tumor, PXA (grade 2) if *with BRAF V600E* activation mutation

Recurrent or Progressive Disease/Useful in Certain Circumstances

- Bullet 3, new: *BRAF* fusion or *BRAF V600E* activating mutation or in NF1-mutated glioma (deleted from Selumetinib)

[GLIO-A \(2 of 9\)](#)

- New: Adjuvant Treatment after surgery/biopsy and treatment with RT and chemotherapy is not preferred WHO grade 2, KPS ≥60. (Also for GLIO-A, 4 of 9)
 - ▶ Preferred Regimen, new: IDH inhibitor (if residual disease is present). (Also for GLIO-A, 4 of 9)
 - ▶ Useful in Certain Circumstances, new: Ivosidenib for *IDH1* mutant grade 2 oligodendroglioma
- New: Adjuvant Treatment after surgery/biopsy, if initial treatment with RT and chemotherapy is preferred or after progression on IDH inhibitor WHO grade 2, KPS ≥60. (Also for GLIO-A, 4 of 9)
 - ▶ Other Recommended Regimens, TMZ and PCV Moved to *Useful in Certain Circumstances*. (Also for GLIO-A, 4 of 9)
- Modified: Adjuvant Treatment, KPS <60, *WHO grade 2, WHO grade 3*
 - ▶ Useful in Certain Circumstances, new: *Ivosidenib* for *IDH1* mutant grade 2
- Modified: Recurrent or Progressive Disease *after RT + chemotherapy* WHO grade 2, KPS ≥60. (Also for GLIO-A, 4 of 9)

[GLIO-A \(3 of 9\)](#)

- Deleted, footnote c: If no prior RT; or if prior RT, consider with highly focused RT in select cases, if new lesion outside target of prior RT or the recurrence is small and geometrically favorable. (Also for GLIO-A, (5 of 9)
- Deleted, footnote k: Consider TMZ if tumor is MGMT promoter methylated. (Also for GLIO-A, (5 of 9)

[GLIO-A \(4 of 9\)](#)

- Useful in Certain Circumstances, new: Ivosidenib for *IDH1* mutant grade 2 astrocytoma

Updates in Version 1.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 1.2023 include:

[GLIO-A \(4 of 9\)](#) (continued)

- Adjuvant Treatment, WHO grade 3 and WHO grade 4, Preferred Regimens, Deleted: number of cycles (~~12 cycles~~) for Standard RT + adjuvant TMZ

[EPEN-2](#)

- Footnote h, 3rd sentence, modified: Lumbar puncture for "prompt" CSF "analysis" should be delayed...(Also for EPEN-3, EPEN-4, AMED-2).

[AMED-A](#)

- Recurrence Therapy
 - ▶ Other Recommended Regimens
 - ◊ New, bullet 3: TMZ/irinotecan/bevacizumab

[PCNS-1](#)

Footnote

- f, modified: Brain biopsy is recommended as the primary procedure to obtain diagnosis. CSF analysis should include flow cytometry, CSF cytology, cell count, and possibly gene rearrangements, *specifically the IGH heavy chain rearrangement*. Polymerase chain reaction (PCR) of MYD88 *in the CSF is helpful*.

[PCNS-2](#)

- Column 2, bullet 7, modified: ~~Whole body PET/CT scan or contrast-enhanced chest/abdomen/pelvis CT~~ ~~Contrast-enhanced chest/abdominal/pelvic CT or whole body PET/CT scan~~

[PCNS-A \(1 of 3\)](#)

- Induction Therapy
 - ▶ Useful in Certain Circumstances
 - ◊ New, bullet 2: Intraocular therapy, High-dose methotrexate
- Relapsed or Refractory Disease
 - ▶ Other Recommended Regimens
 - ◊ New, bullet 9: rituximab, methotrexate, carmustine, etoposide, and prednisone (R-MBVP)

[PSCT-2](#)

Pathology

- Bullet 2, sub-bullet 1, modified: ~~Consider~~ Screening for von Hippel-Lindau (VHL) syndrome

Reference

- Deleted: VHL Family Alliance: The VHL Handbook: What You Need to Know About VHL: A Reference Handbook for People with von Hippel-Lindau Disease, Their Families, and Support Personnel. Boston, MA, 2014 VHL Family Alliance.

[PSCT-3](#)

Footnote

- New: For Neurofibromatosis type 2 vestibular schwannomas with hearing loss, see [BRAIN-D 3 of 5](#).

[PSCT-A](#)

- Miscellaneous CNS Tumors
 - ▶ Other Recommended Regimens
 - ◊ Modified to include Bevacizumab
 - ▶ Useful in Certain Circumstances
 - ◊ Modified: Belzutifan (VHL-associated CNS hemangioblastomas not requiring immediate surgery *or those for whom surgery is contraindicated due to location or prior surgeries or comorbidities, growing or symptomatic*)

Updates in Version 1.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 1.2023 include:

[MENI-1](#)

- Column 2, bullet 2, modified: Consider octreotide scan or DOTATATE PET/CT or *PET/MRI* scan if diagnostic doubt exists. (Also for MENI-2)
- Column 3, bullet 2, new: Consider clinical trial (for cases that are not surgically accessible but for which treatment with RT and/or systemic therapy is considered)

[BRAIN METS-A \(1 of 4\)](#)

- Tumor Agnostic
 - ▶ New: MSI-H/dMMR or TMB-H tumors for isolated brain metastases
 - ◊ Preferred Regimen: Pembrolizumab (category 2B)
- Non-Small Cell Lung Cancer (NSCLC)
 - ◊ Sub, sub-bullet 2, new: Sotorasib (category 2B)
- Renal Cell Carcinoma
 - ▶ Sub-bullet 2, new: Belzutifan (category 2B) (for VHL-associated RCC)

[LEPT-1](#)

Footnote

- d, 2nd sentence, modified: When available, assessment of circulating tumor DNA (ctDNA) or *circulating tumor cells (CTCs)* increases sensitivity of tumor cell detection and assessment of response to treatment. For hematologic malignancies, use flow cytometry.

[LEPT-2](#)

- Column 2, bullet 3, deleted: SRS or RT (involved-field and/or whole brain) to bulky disease and neurologically symptomatic (such as cranial neuropathies) or painful sites. Consider craniospinal irradiation (CSI) in select patients.
- Column 2, bullet 3, new: Radiation therapy
 - ▶ Consider involved-field RT (eg, partial or WBRT, skull base RT, focal spine RT) to bulky disease for focal disease control and to neurologically symptomatic or and painful sites
 - ▶ Consider craniospinal irradiation (CSI) for CNS and CSF disease control in select patients with or without symptoms

Footnote

- k, modified: ~~Due to substantial toxicity, conventional photon-based craniospinal RT should only be considered in highly select patients (eg, leukemia, lymphoma).~~ Use of advanced modalities to minimize toxicity, *including techniques in maximizing bone marrow sparing*, is recommended when considering craniospinal RT (eg, protons when available [Yang JT, et al. J Clin Oncol 2022;40:3858-3867], or conformal photon-based techniques/IMRT). In addition, ~~weekly careful assessment and~~ monitoring of blood counts should be performed given risk of hematologic toxicity.

[LEPT-A](#)

- Melanoma, new
 - ▶ Useful in Certain Circumstances
 - ◊ IT and IV nivolumab (category 2B)

[SPINE-3](#)

- Column 4, lower pathway, modified: Consider surgery + ~~RT with or without RT~~

[Continued](#)

UPDATES

Updates in Version 1.2024 of the NCCN Guidelines for Central Nervous System Cancers from Version 1.2023 include:

[BRAIN-B](#)

[Options](#)

- Bullet 3, sub-bullet 1, modified: LITT may be considered for patients who are poor surgical candidates (craniotomy or resection). Potential indications include relapsed brain metastases, radiation necrosis, ~~and recurrent glioblastomas,~~ *and other gliomas*

[BRAIN-C](#)

[Principles of Radiation Therapy for Brain and Spinal Cord](#)

- This section of the guideline has been significantly updated.

[BRAIN-D](#)

[Principles of Brain and Spine Tumor Management](#)

- This section of the guideline has been significantly updated.

[BRAIN-E \(1 of 9\)](#)

[Principles of Brain Tumor Pathology](#)

- Updated: WHO 2021 ~~2016~~ Classification of Tumors of the Central Nervous System

[BRAIN-E \(2 of 9\)](#)

[Principles of Brain Tumor Pathology: Molecular Markers](#)

[Molecular Characterization](#)

- Bullet 3, new: Next-generation sequencing (NGS) is now the preferred approach for pathologic workup of CNS tumors, as it screens for multiple diagnostic and prognostic mutations in one test.
- Bullet 4, new: NGS results from tumor tissue cannot prove the existence of a heritable cancer predisposition syndrome (eg, Lynch syndrome, Li-Fraumeni syndrome). If such a syndrome is suspected based on clinical and family history, genetic counseling and testing of "germline" DNA from the bloodstream is required.

[BRAIN-E \(3 of 9\)](#)

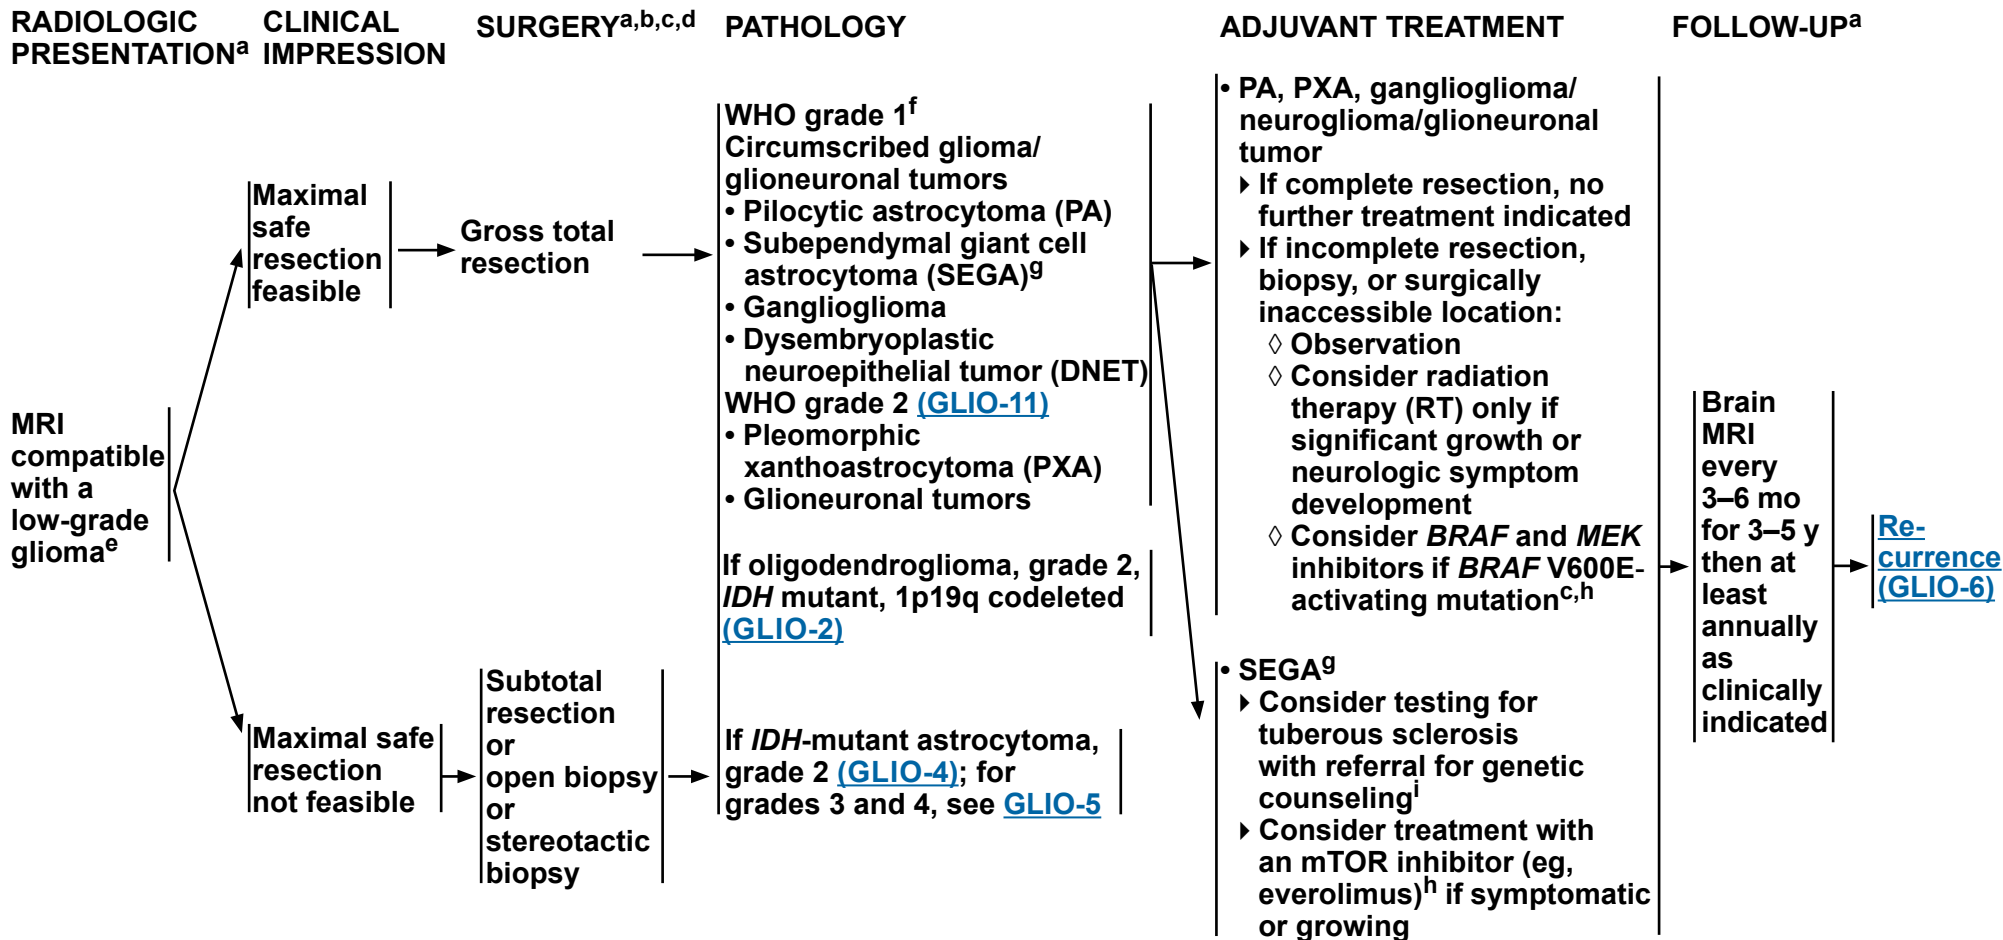

[MGMT Promoter Methylation](#)

- Bullet 3, 2nd sentence, modified: One study suggested that pyrosequencing is the best prognostic stratifier among *glioblastomas* ~~glioblastoma-multiforme~~ treated with TMZ

[BRAIN-E \(6 of 9\)](#)

[Ependymomas](#)

- Sub-sub-bullet 5, deleted: PFA vs. PFB via methylation profiling is reasonable for posterior fossa ependymoma.

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^b [Principles of Brain Tumor Surgery \(BRAIN-B\)](#).

^c For recommended molecular diagnostics, see [Principles of Brain Tumor Pathology \(BRAIN-E\)](#).

^d Postoperative brain MRI within 48 hours after surgery.

^e Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^f WHO grade 1 tumors with concurrent *H3* and *BRAF* alterations may behave more aggressively. See [Principles of Brain Tumor Pathology \(BRAIN-E\)](#).

^g The need to treat SEGAs or other findings in the appropriate tuberous sclerosis patient population should be determined by the patient's symptoms and/or change on serial radiologic studies. Referral to medical genetics/brain tumor center is recommended.

^h [Systemic Therapy Options \(GLIO-A\)](#).

NCCN Guidelines Version 3.2024

Adult Glioma: Oligodendroglioma (IDH-Mutant, 1p19q codeleted)

PATHOLOGY^{c,e}

ADJUVANT TREATMENT

FOLLOW-UP^a

Note: All recommendations are category 2A unless otherwise indicated.

FOOTNOTES

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^c For recommended molecular diagnostics, see [Principles of Brain Tumor Pathology \(BRAIN-E\)](#).

^e Based on multidisciplinary review for treatment planning, once pathology is available. [See Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^h [Systemic Therapy Options \(GLIO-A\)](#).

^j Regular follow-up is essential for patients receiving observation alone after resection.

^k Vorasidenib is a dual inhibitor of *IDH1* and *IDH2* mutations. In a phase 3 study of vorasidenib versus placebo (Mellinghoff IK, et al. N Engl J Med 2023;389:589-601) in patients with residual or recurrent grade 2 *IDH*-mutant glioma (after surgery and no prior treatment), vorasidenib improved median PFS (27.7 mo vs. 11.1 mo), compared to placebo.

^l The results of RTOG 9802 showed that there was a significant improvement in median overall survival in patients with high-risk low-grade glioma treated with RT followed by PCV x 6 cycles compared with RT alone after a tissue diagnosis was made. However, this important study did not address whether all of these patients should be treated right away. Observation after diagnosis or treatment with an *IDH* inhibitor may be reasonable options for a patient with low-grade glioma who is neurologically asymptomatic or stable. Close monitoring with brain MRIs is important.

^m [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

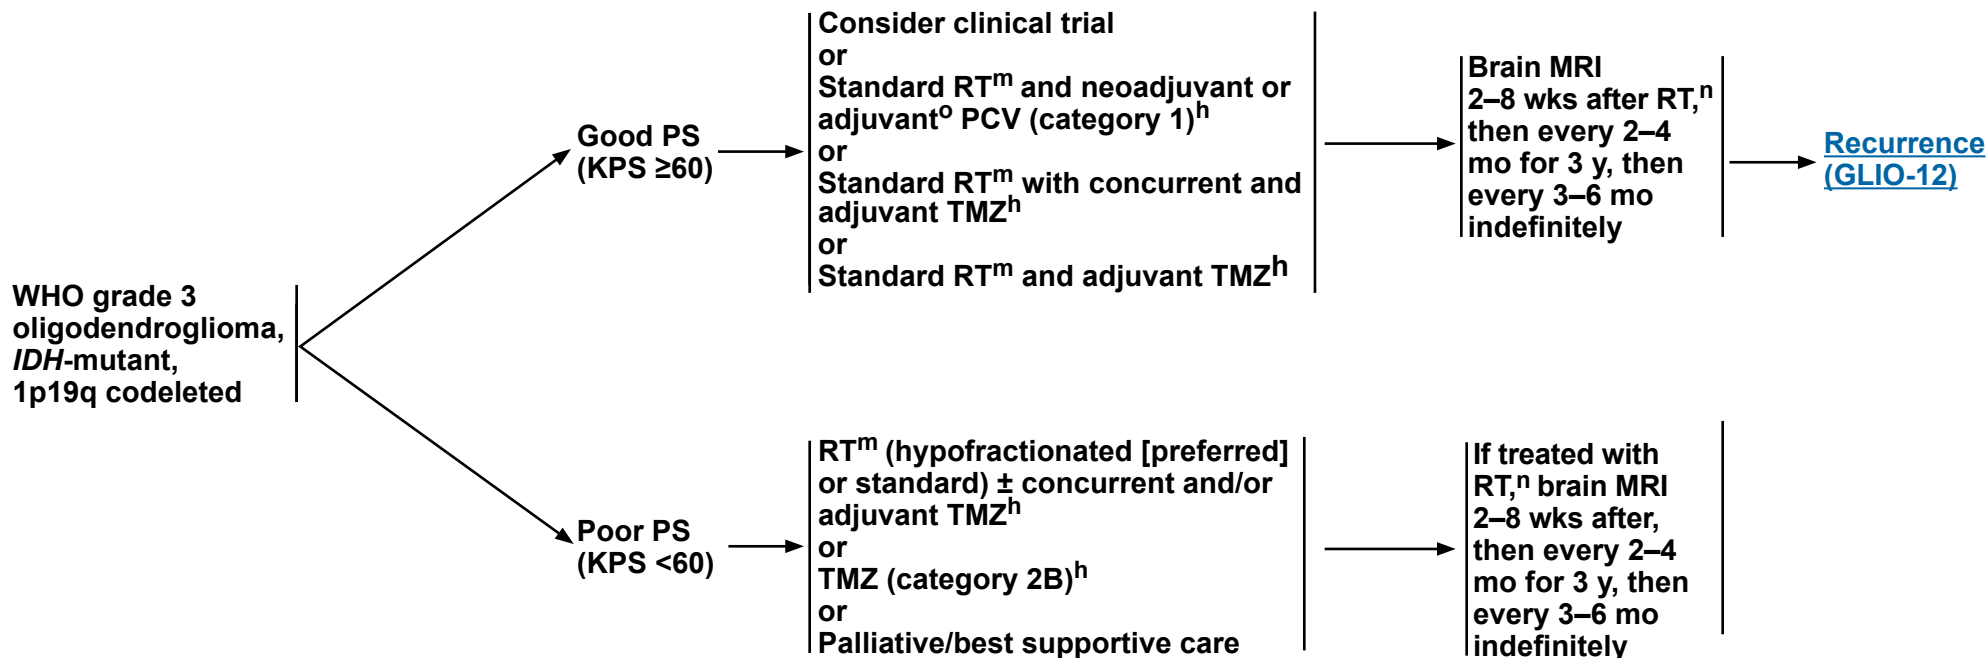

ⁿ Within the first 3 months after completion of RT and concomitant TMZ, diagnosis of recurrence can be indistinguishable from pseudoprogression on neuroimaging.

Note: All recommendations are category 2A unless otherwise indicated.

^h [Systemic Therapy Options \(GLIO-A\)](#).

^j Regular follow-up is essential for patients receiving observation alone after resection.

^k Vorasidenib is a dual inhibitor of *IDH1* and *IDH2* mutations. In a phase 3 study of vorasidenib versus placebo (Mellinghoff IK, et al. *N Engl J Med* 2023;389:589-601) in patients with residual or recurrent grade 2 *IDH*-mutant glioma (after surgery and no prior treatment), vorasidenib improved median PFS (27.7 mo vs. 11.1 mo), compared to placebo.

^l The results of RTOG 9802 showed that there was a significant improvement in median overall survival in patients with high-risk low-grade glioma treated with RT followed by PCV x 6 cycles compared with RT alone after a tissue diagnosis was made. However, this important study did not address whether all of these patients should be treated right away. Observation after diagnosis or treatment with an *IDH* inhibitor may be reasonable options for a patient with low-grade glioma who is neurologically asymptomatic or stable. Close monitoring with brain MRIs is important.

^m [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

ⁿ Within the first 3 months after completion of RT and concomitant TMZ, diagnosis of recurrence can be indistinguishable from pseudoprogression on neuroimaging.

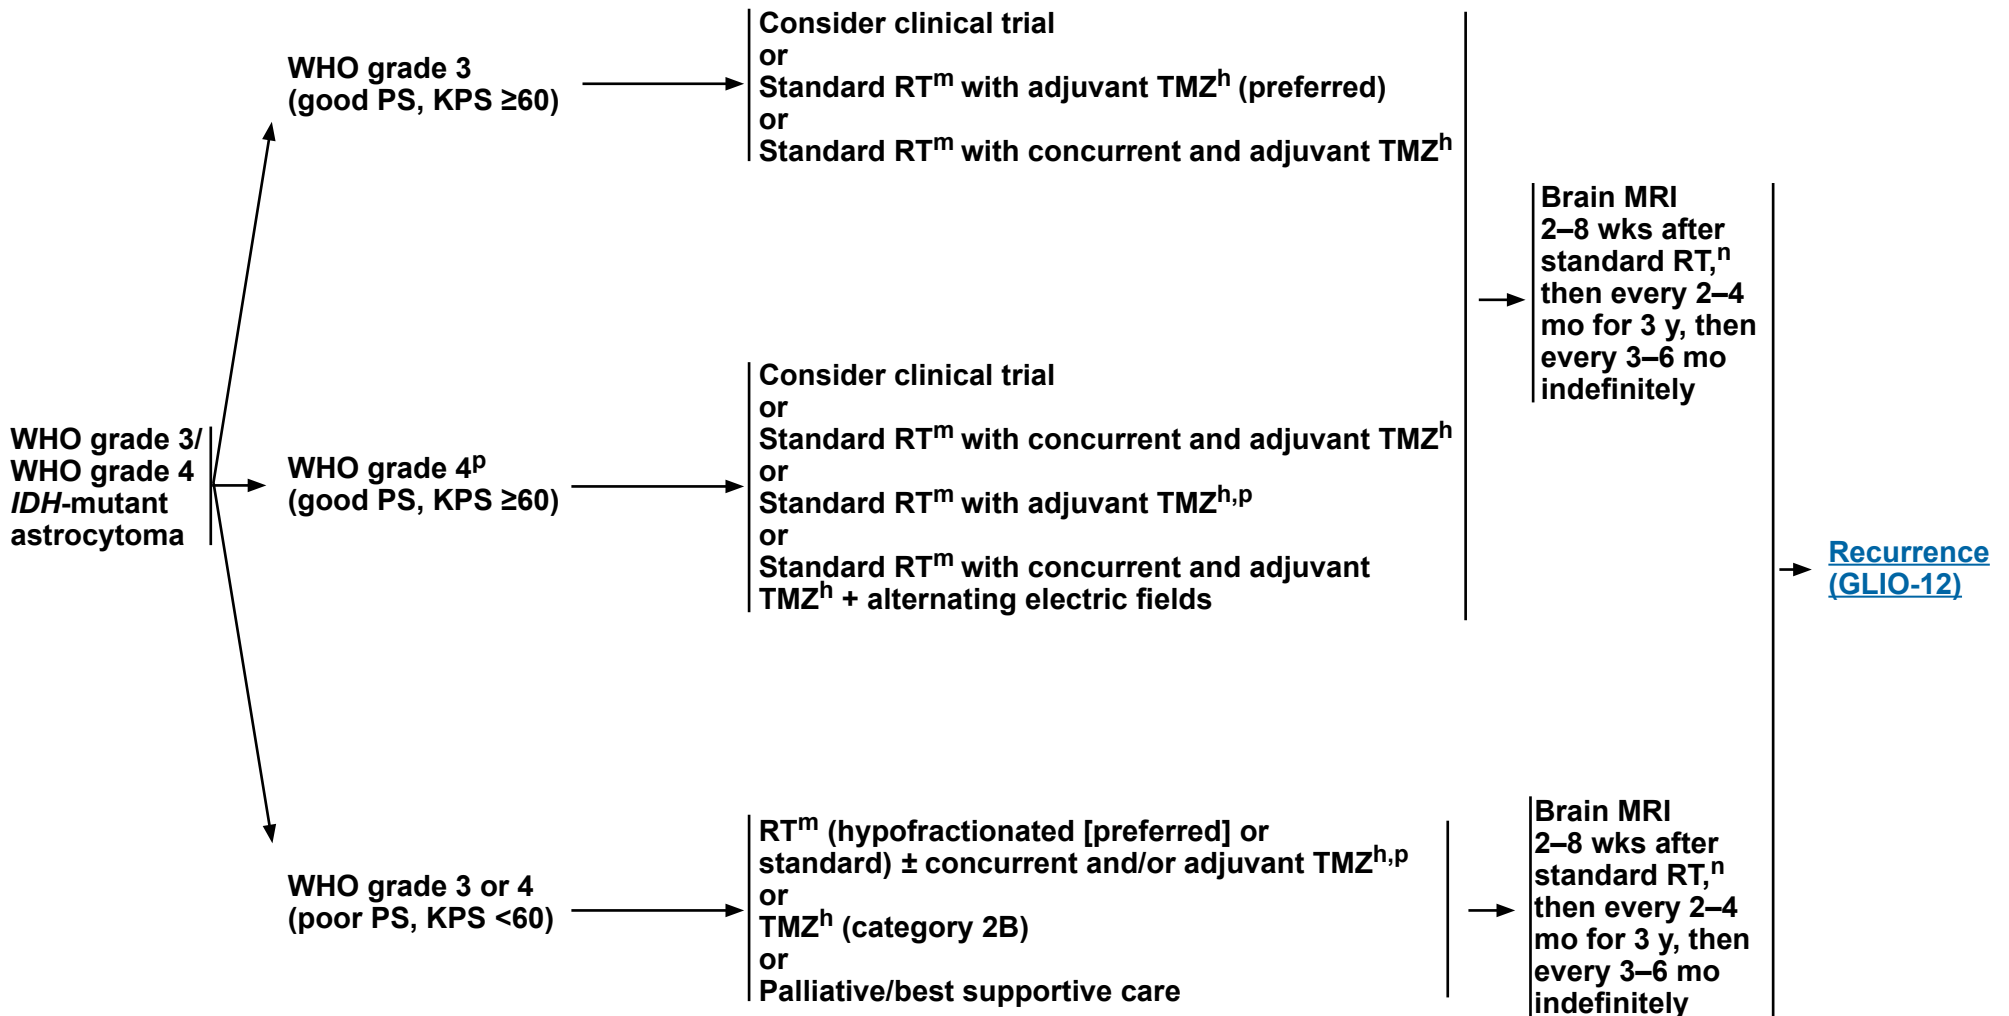

Note: All recommendations are category 2A unless otherwise indicated.

NCCN Guidelines Version 3.2024

Adult Glioma: Recurrent or Progressive Circumscribed Glioma

RECURRENCE

TREATMENT

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^d Postoperative brain MRI within 48 hours after surgery.

^e Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^h [Systemic Therapy Options \(GLIO-A\)](#).

^m [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^t If radiographically the tumor appears to be a high-grade glioma, see [GLIO-8](#).

^q Recurrence on neuroimaging can be confounded by treatment effects. To confirm tumor recurrence and assess for possible transformation of tumor to higher grade, strongly consider tumor tissue sampling (biopsy at minimum) if there is a high index of suspicion of recurrence. For treatment of patients with transformation to high-grade disease, see [GLIO-8](#).

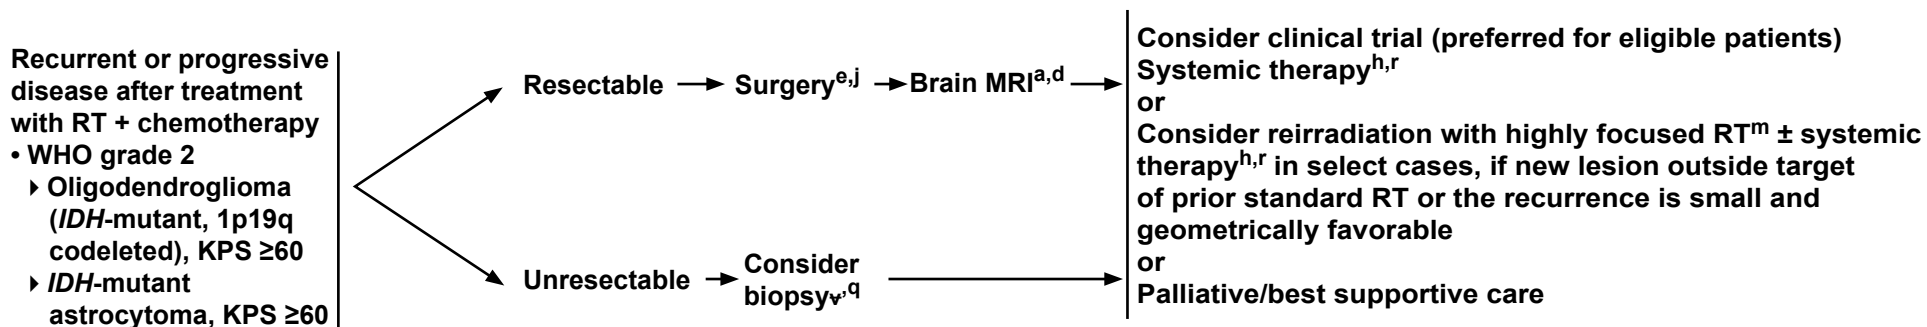

^r Brain MRI every 2–3 months while on treatment, to assess disease recurrence/progression ([BRAIN-A](#)).

^s RT alone is not encouraged, but may be appropriate for select cases (eg, poor PS).

Note: All recommendations are category 2A unless otherwise indicated.

RECURRENCE^j

TREATMENT

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^d Postoperative brain MRI within 48 hours after surgery.

^e Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^h [Systemic Therapy Options \(GLIO-A\)](#).

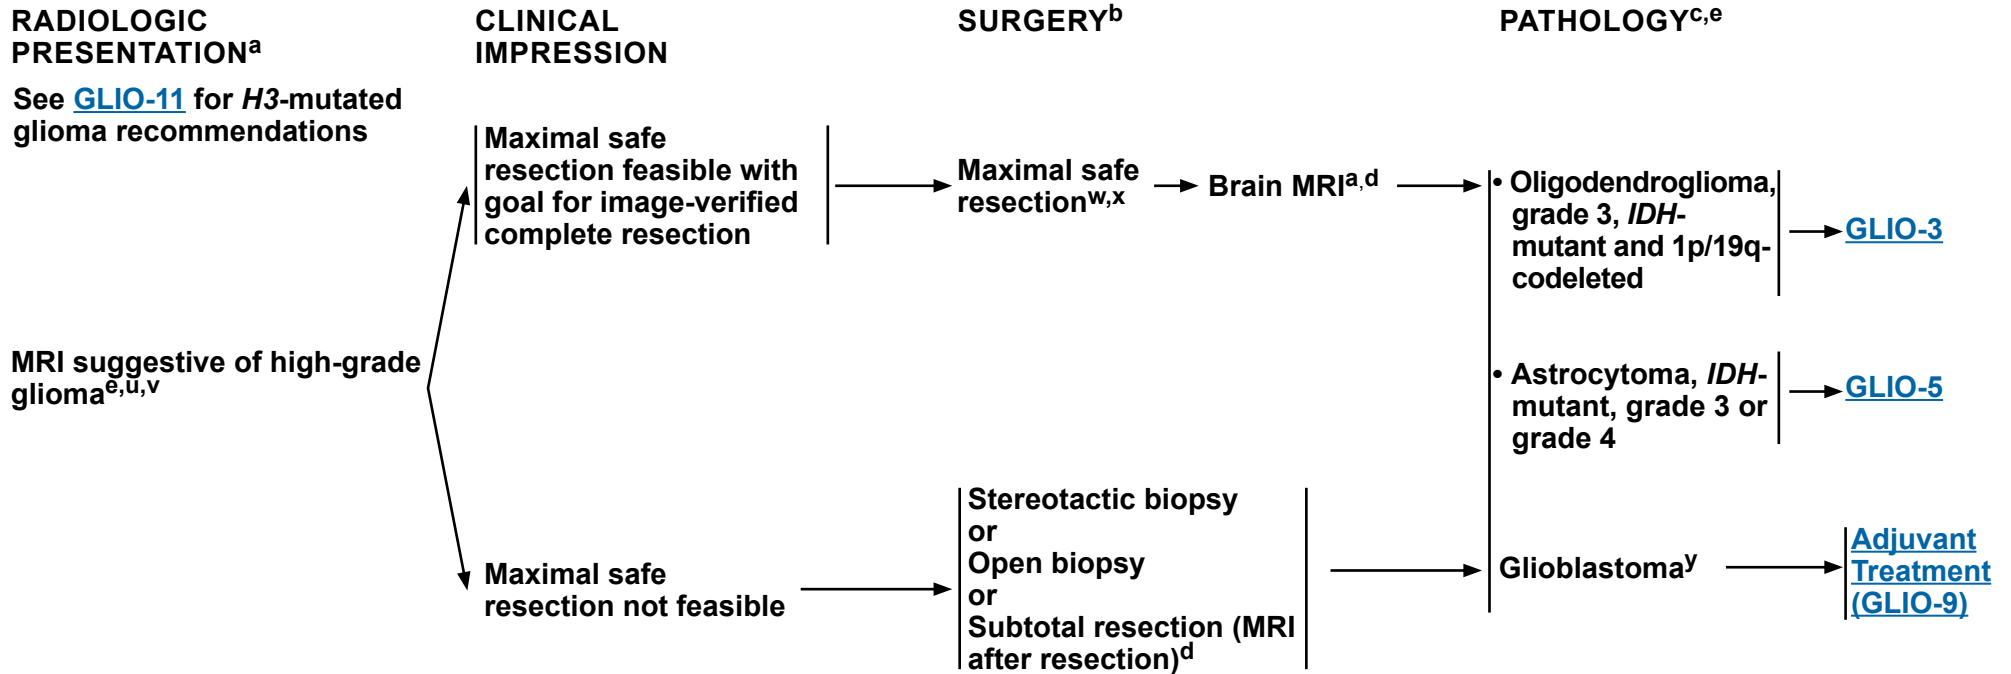

^j Regular follow-up is essential for patients receiving observation alone after resection.

^m [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^q Recurrence on neuroimaging can be confounded by treatment effects. To confirm tumor recurrence and assess for possible transformation of tumor to higher grade, strongly consider tumor tissue sampling (biopsy at minimum) if there is a high index of suspicion of recurrence. For treatment of patients with transformation to high-grade disease, see [GLIO-8](#).

^r Brain MRI every 2–3 months while on treatment, to assess disease recurrence/progression ([BRAIN-A](#)).

^{ee} Clinical benefit from TMZ is likely to be lower in patients whose tumors lack MGMT promoter methylation.

^{ff} [NCCN Guidelines for Older Adult Oncology](#).

^{gg} Hypofractionated RT and TMZ have not been formally compared with standard RT and TMZ in patients aged >70 y.

Note: All recommendations are category 2A unless otherwise indicated.

PATHOLOGY ^c	MGMT PROMOTER STATUS	ADJUVANT TREATMENT	FOLLOW-UP ^a
------------------------	----------------------	--------------------	------------------------

The treatment recommendations on this page are general high-grade glioma options. Tumor MGMT status and NGS should be performed to possibly expand therapeutic options.

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^c For recommended molecular diagnostics, see [Principles of Brain Tumor Pathology \(BRAIN-E\)](#).

^m [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

ⁿ Within the first 3 months after completion of RT and concomitant TMZ, diagnosis of recurrence can be indistinguishable from pseudoprogression on neuroimaging.

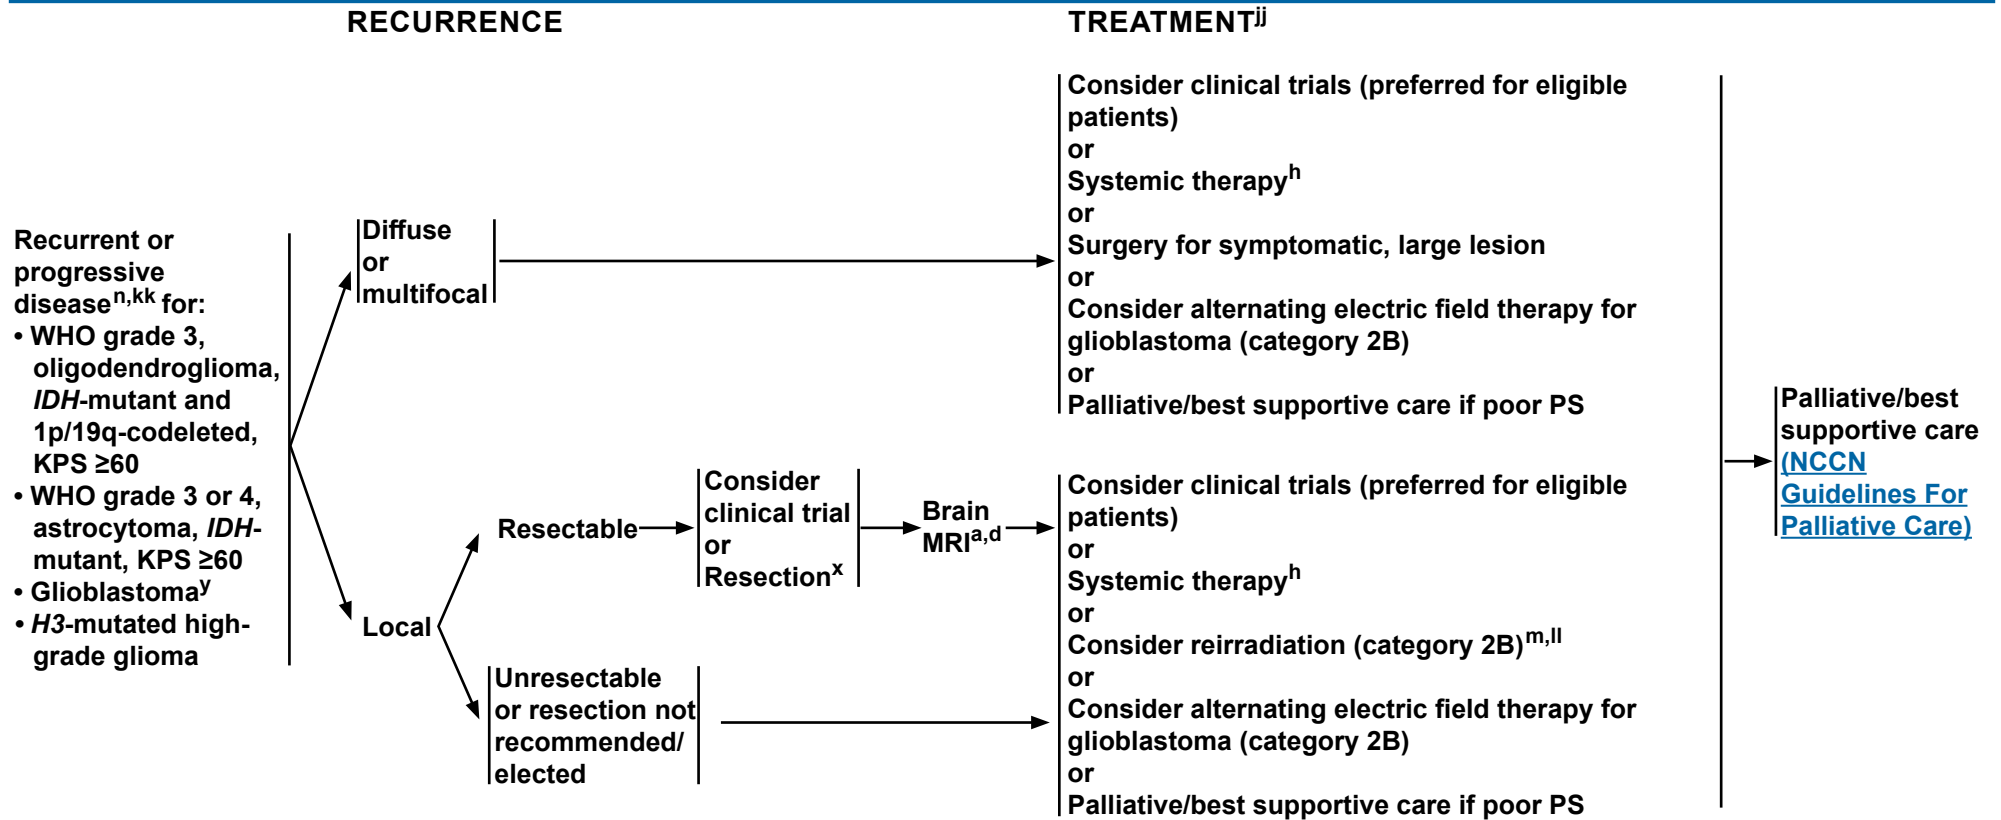

^{hh} Consider pyrosequencing if not done (Mansouri A, et al. Neuro Oncol 2019;21:167-178).

ⁱⁱ Systemic therapy options for the more common recurrent high grade gliomas (glioblastoma, grade 3 oligodendroglioma, and grade 3 or 4 astrocytoma) also apply to these other high-grade gliomas. See [GLIO-A 6 of 9](#).

Note: All recommendations are category 2A unless otherwise indicated.

NCCN Guidelines Version 3.2024

Adult Glioma: Recurrent or Progressive Disease (WHO Grades 3 & 4)

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^d Postoperative brain MRI within 48 hours after surgery.

^h [Systemic Therapy Options \(GLIO-A\)](#).

^m [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

ⁿ Within the first 3 months after completion of RT and concomitant TMZ, diagnosis of recurrence can be indistinguishable from pseudoprogression on neuroimaging.

^x Consider carmustine (BCNU) wafer implant during maximal safe resection (category 2B). Treatment with carmustine wafer may impact enrollment in adjuvant clinical trials.

^y This pathway also includes gliosarcoma.

^{jj} The efficacy of standard-of-care treatment for recurrent glioblastoma is suboptimal, so for eligible patients consideration of clinical trials is highly encouraged. Prior treatment may impact enrollment in clinical trials.

^{kk} Consider biopsy, MR spectroscopy, MR perfusion, brain PET/CT, or brain PET/MRI, or re-image to follow changes that may be due to progression versus radionecrosis.

^{ll} Especially if long interval since prior RT and/or if there was a good response to prior RT (RTOG 1205; Tsien CI, et al. J Clin Oncol 2023;41:1285-1295).

Note: All recommendations are category 2A unless otherwise indicated.

NCCN Guidelines Version 3.2024 Adult Intracranial and Spinal Ependymoma (Excluding Subependymoma)

**RADIOLOGIC
PRESENTATION^a**

**CLINICAL
IMPRESSION**

SURGERY^d

PATHOLOGY^e

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^b Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-E\)](#).

^c If image-confirmed gross total resection not achieved, consider multidisciplinary review and resection.

^d [Principles of Brain Tumor Surgery \(BRAIN-B\)](#).

^e [Principles of Brain Tumor Pathology \(BRAIN-E\)](#).

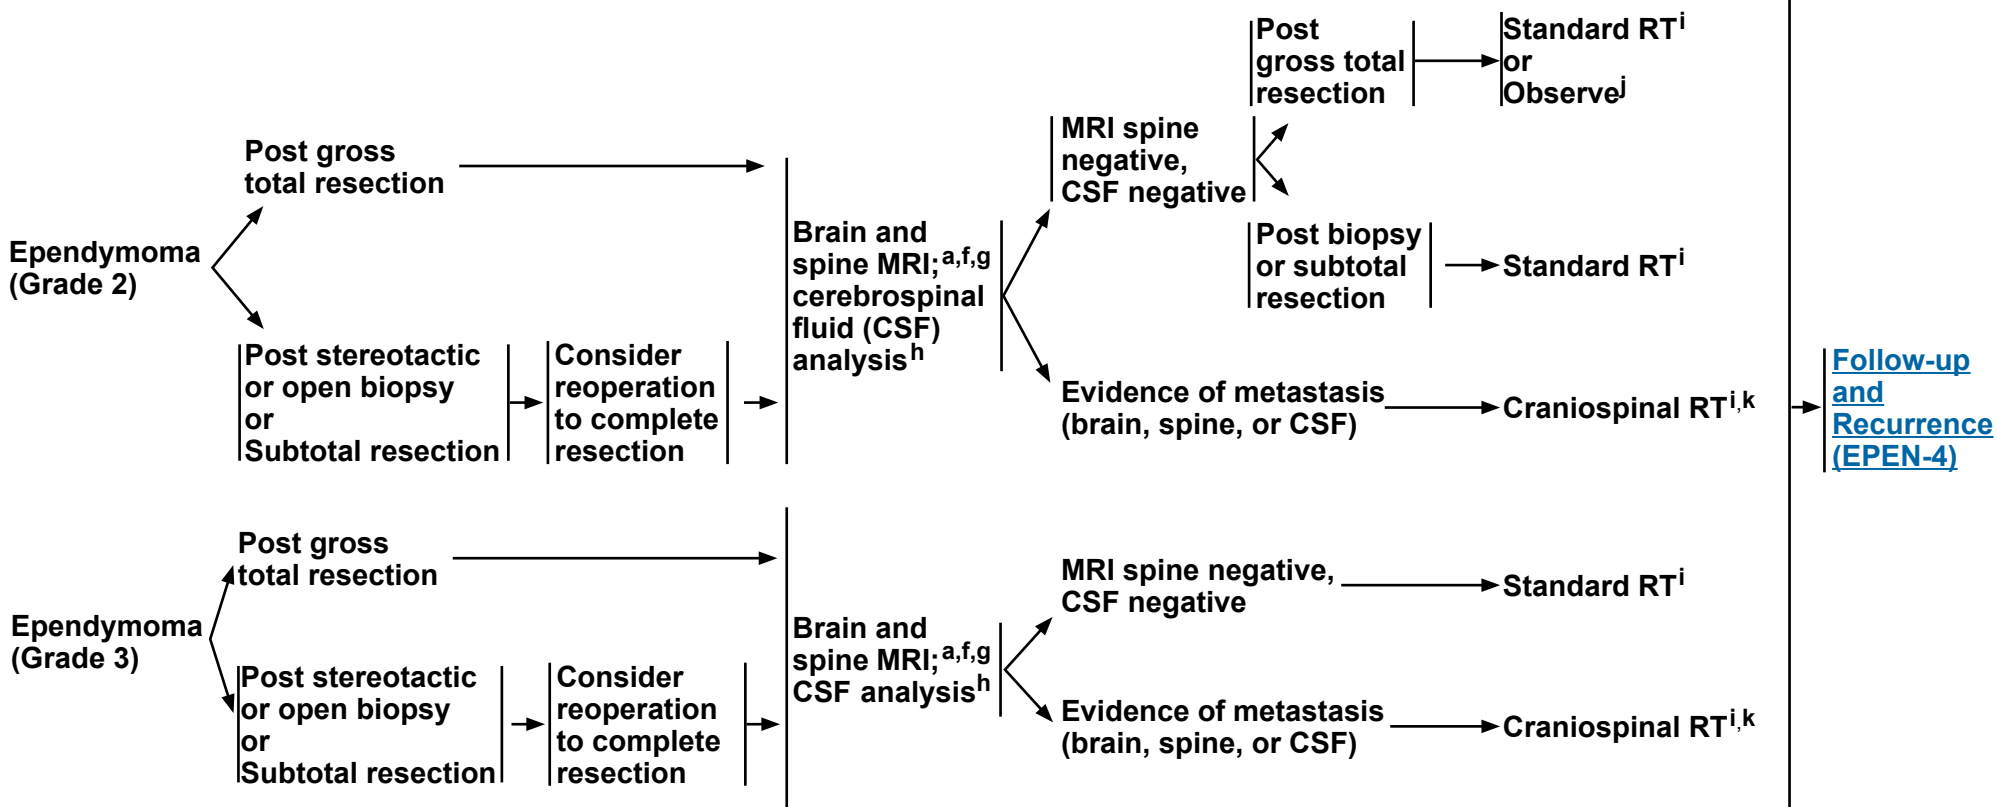

Note: All recommendations are category 2A unless otherwise indicated.

INTRACRANIAL EPENDYMOMA

PATHOLOGY

POSTOPERATIVE STAGING

ADJUVANT TREATMENTⁱ

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^f Postoperative brain MRI within 48 hours after surgery.

^g If not done preoperatively, spine MRI should be delayed by at least 2–3 weeks post surgery to avoid post-surgical artifacts.

^h Lumbar puncture is indicated when there is clinical concern for meningeal dissemination. Lumbar puncture should be done after MRI of spine is performed to avoid a false-positive imaging result. Lumbar puncture for prompt CSF analysis should be delayed at least 2 weeks after surgery to avoid possible false-positive cytology. Lumbar puncture may be contraindicated (eg, posterior fossa mass).

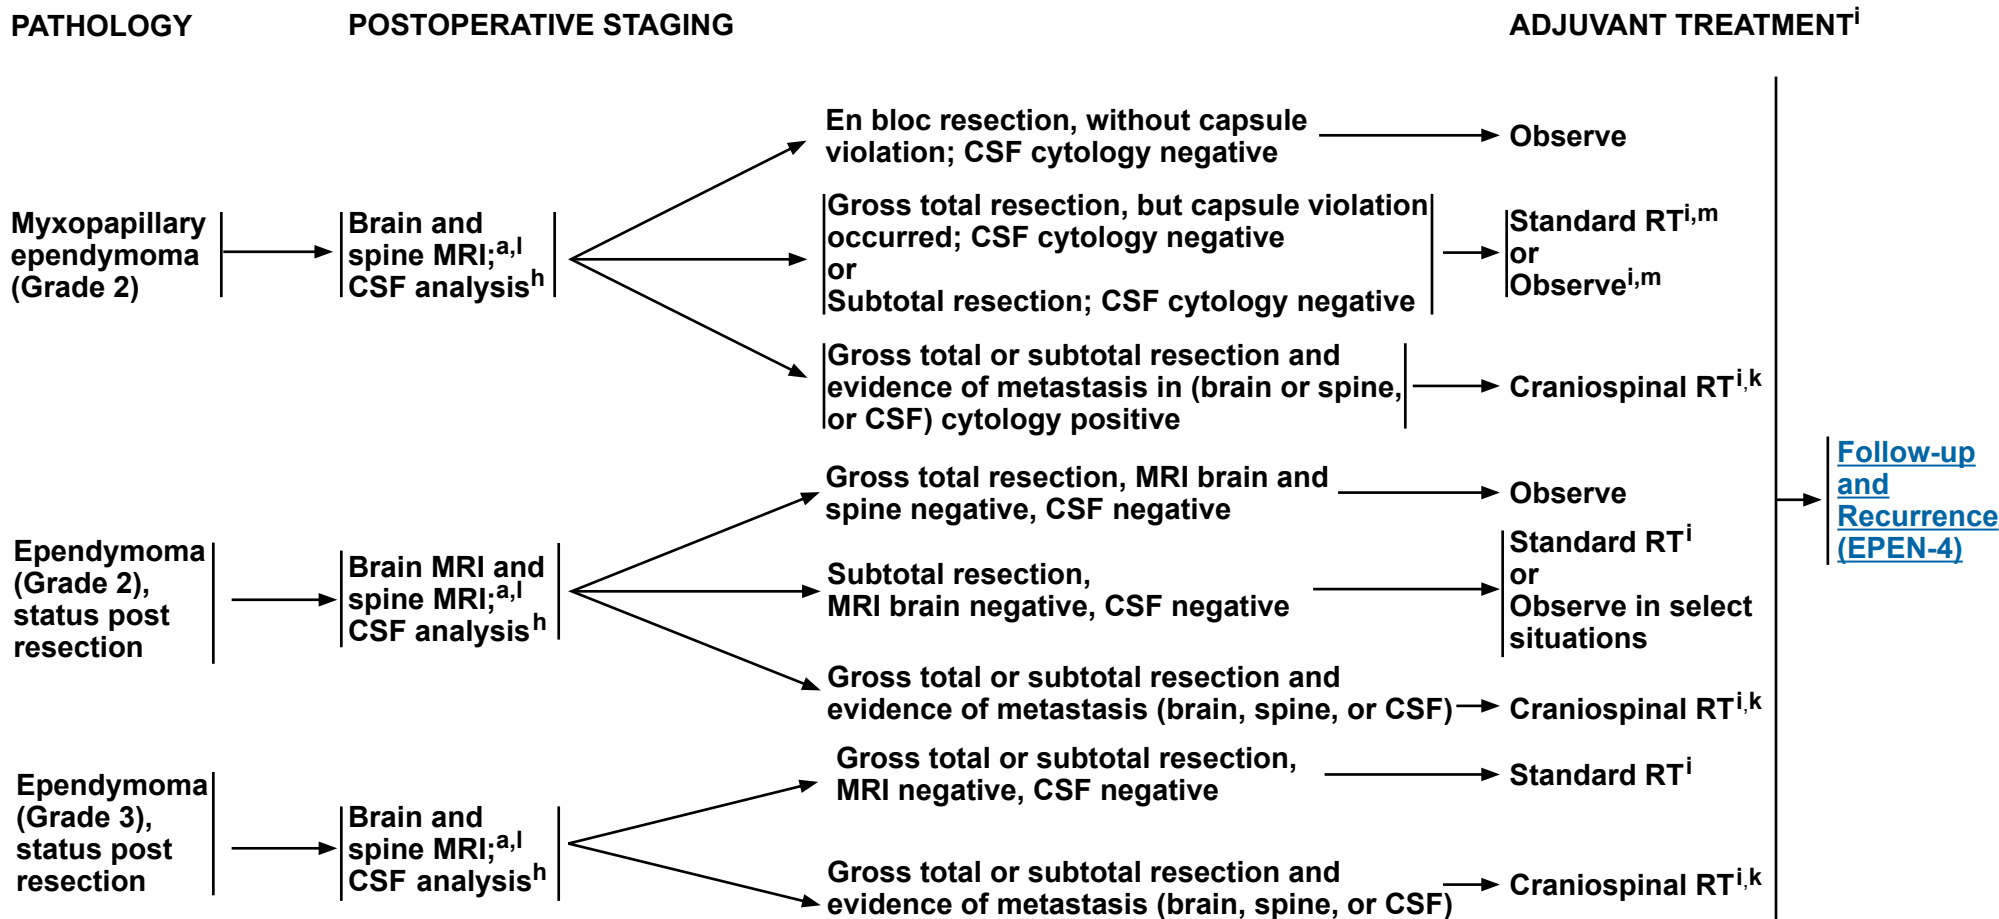

ⁱ [Principles Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^j Data supporting observation alone are based on retrospective studies.

^k Consider proton therapy or intensity-modulated RT (IMRT) if available to reduce toxicity (Barney CL, et al. Neuro Oncol 2014;16:303-309).

Note: All recommendations are category 2A unless otherwise indicated.

SPINAL EPENDYMOMA

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^h Lumbar puncture is indicated when there is clinical concern for meningeal dissemination. Lumbar puncture should be done after MRI of spine is performed to avoid a false-positive imaging result. Lumbar puncture for prompt CSF analysis should be delayed at least 2 weeks after surgery to avoid possible false-positive cytology. Lumbar puncture may be contraindicated (eg, posterior fossa mass).

ⁱ [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^k Consider proton therapy or IMRT if available to reduce toxicity (Barney CL, et al. Neuro Oncol 2014;16:303-309).

^l If not done preoperatively, spine MRI should be performed 48 h post surgery.

^m RT has been associated with improved disease control (Weber D, et al. Neuro Oncol 2015;17:588-595). Given the potential for salvage therapy, close observation may be clinically appropriate in some cases (Kotecha R, et al. J Neurosurg Spine 2020;1:1-6).

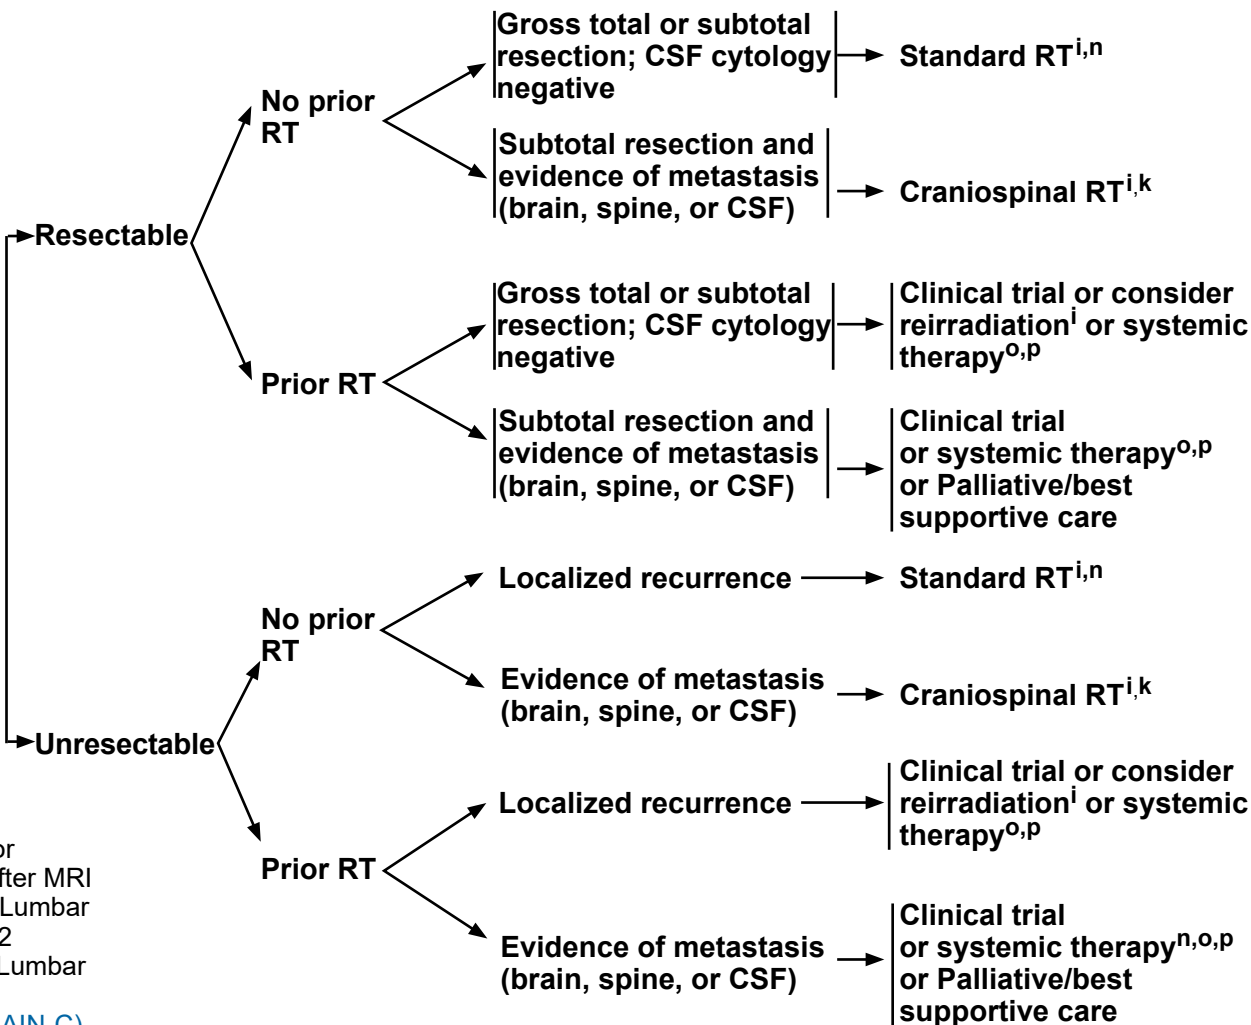

Note: All recommendations are category 2A unless otherwise indicated.

FOLLOW-UP^a

RECURRENCE STAGING WORKUP^a

TREATMENT FOR PROGRESSION OR RECURRENCE

- Imaging in the event of emergent signs or symptoms (brain and/or spine MRI)
- Imaging of tumor site (brain or spine MRI) every 3–4 mo for 1 y, then every 4–6 mo for year 2, then every 6–12 mo for 5–10 y, then as clinically indicated

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^h Lumbar puncture is indicated when there is clinical concern for meningeal dissemination. Lumbar puncture should be done after MRI of spine is performed to avoid a false-positive imaging result. Lumbar puncture for prompt CSF analysis should be delayed at least 2 weeks after surgery to avoid possible false-positive cytology. Lumbar puncture may be contraindicated (eg, posterior fossa mass).

ⁱ [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^k Consider proton therapy or IMRT if available to reduce toxicity (Barney CL, et al. Neuro Oncol 2014;16:303-309).

ⁿ Consider stereotactic radiosurgery (SRS) if geometrically favorable.

^o Systemic therapy should be reserved for patients who are refractory to surgery or radiation.

^p [Adult Intracranial and Spinal Ependymoma Systemic Therapy \(EPEN-A\)](#).

Note: All recommendations are category 2A unless otherwise indicated.

ADULT INTRACRANIAL AND SPINAL EPENDYMOMA (EXCLUDING SUBEPENDYMOMA): SYSTEMIC THERAPY

	Preferred Regimens	Other Recommended Regimens	Useful in Certain Circumstances
Recurrence Therapy	<ul style="list-style-type: none"> • None 	<ul style="list-style-type: none"> • Platinum-based regimens:^a Single agent or combination^{1,2} • Etoposide^{3,4} • Lomustine or carmustine¹ • Bevacizumab^{b,c,5} • TMZ⁶ • Lapatinib + TMZ (category 2B)⁷ 	<ul style="list-style-type: none"> • None

FOOTNOTES

^a Platinum-based regimens include cisplatin or carboplatin.

^b Patients who have evidence of radiographic progression may benefit from continuation of bevacizumab to prevent rapid neurologic deterioration.

^c An FDA-approved biosimilar is an appropriate substitute for bevacizumab.

Note: All recommendations are category 2A unless otherwise indicated.

RADIOLOGIC PRESENTATION^a

CLINICAL IMPRESSION

SURGERY^d

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^b Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^c Placement of ventriculoperitoneal (VP) shunt for management of hydrocephalus is acceptable if needed.

^d [Principles of Brain Tumor Surgery \(BRAIN-B\)](#).

^e Strongly recommend referring patient to a brain tumor center to be evaluated for possible further, more complete surgical resection.

Note: All recommendations are category 2A unless otherwise indicated.

POSTOPERATIVE STAGING

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^f Postoperative brain MRI within 48 hours after surgery.

^g Spine MRI should be delayed by at least 2–3 weeks post surgery to avoid post-surgical artifacts.

^h Lumbar puncture should be done after spine MRI. Lumbar puncture for prompt CSF analysis should be delayed at least 2 weeks after surgery to avoid possible false-positive cytology.

ⁱ Bone scan; CT with contrast of chest, abdomen, and pelvis or whole body PET/CT; and bone marrow biopsy only if clinically indicated.

^j Molecular profiling to identify clinically relevant subtypes is recommended to encourage opportunities for clinical trial involvement. See [Principles of Brain Tumor Pathology \(BRAIN-E\)](#).

^k See the modified Chang system for staging medulloblastoma. [Chang CH, Housepain EM, Herbert C. Radiology 1969;93:1351-1359 and Cohen ME, Duffner PK (Eds). Brain tumors in children, 2nd ed, McGraw-Hill, New York, 1994, p.187.]

^l Since adult medulloblastoma is a rare adult central nervous system (CNS) malignancy, patients should be considered for referral to specialized brain tumor centers. We strongly recommend consideration of specialized surgical evaluation given the impact of resection on survival, reproductive endocrine and fertility evaluation, stem cell collection, role of early neuro-rehabilitation, and avoiding delay in adjuvant treatment initiation. Patients with a rare CNS tumor should be considered for registration in national registries of rare tumors. See <https://clinicaltrials.gov/ct2/show/NCT02851706>.

^m [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

ⁿ Consider proton therapy if available to reduce toxicity.

^o Omission of vincristine during radiotherapy phase of therapy or dose modification may be required for adults because they do not tolerate this regimen as well. Data supporting vincristine's use have been found in pediatric trials only. Patients should be closely monitored for neurologic toxicity with periodic exams. (Packer RJ, Gajjar A, Vezina G, et al. Phase III study of craniospinal radiation therapy followed by adjuvant systemic therapy for newly diagnosed average-risk medulloblastoma. J Clin Oncol 2006;24:4202-4208.)

^p [Adult Medulloblastoma Systemic Therapy \(AMED-A\)](#).

^q Consider collecting stem cells before craniospinal radiation.

Note: All recommendations are category 2A unless otherwise indicated.

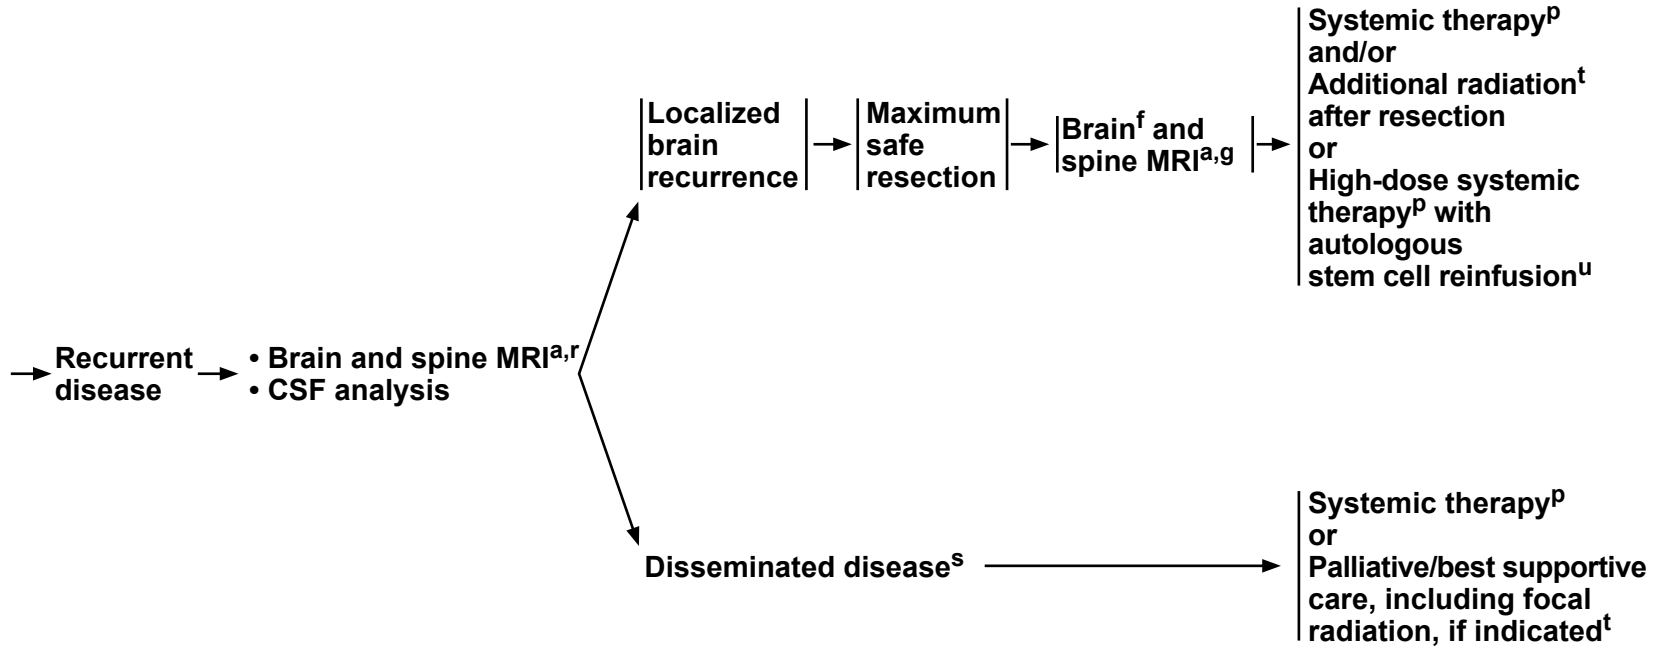

FOLLOW-UP^a

CLINICAL STAGING

SURGERY

TREATMENT FOR RECURRENCE

Brain MRI:
every 3 mo for 2 y;
then every 6–12 mo
for 5–10 y; then every
1–2 y or as clinically
indicated
For patients with
previous spine disease,
concurrent spine
imaging as clinically
indicated

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^f Postoperative brain MRI within 48 hours after surgery.

^g Spine MRI should be delayed by at least 2–3 weeks post surgery to avoid post-surgical artifacts.

^p [Adult Medulloblastoma Systemic Therapy \(AMED-A\)](#).

^r As clinically indicated, consider bone scan; contrast-enhanced CT scans of chest, abdomen, and pelvis; and/or bone marrow biopsy.

^s Consider resection for palliation of symptoms where indicated.

^t [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^u Only if the patient is without evidence of disease after surgery or conventional dose re-induction systemic therapy.

Note: All recommendations are category 2A unless otherwise indicated.

ADULT MEDULLOBLASTOMA: SYSTEMIC THERAPY

	<u>Preferred Regimens</u>	<u>Other Recommended Regimens</u>	<u>Useful in Certain Circumstances</u>
Regimens Following Weekly Vincristine^a During Craniospinal RT	<ul style="list-style-type: none"> • Cisplatin, cyclophosphamide, and vincristine^{a,1} • Cisplatin, lomustine, and vincristine^{a,1} 	<ul style="list-style-type: none"> • None 	<ul style="list-style-type: none"> • None
Recurrence Therapy	<ul style="list-style-type: none"> • None 	<ul style="list-style-type: none"> • No prior systemic therapy <ul style="list-style-type: none"> ▶ High-dose cyclophosphamide ± etoposide ▶ Carboplatin, etoposide, and cyclophosphamide^{2,3} ▶ Cisplatin, etoposide, and cyclophosphamide² • Prior systemic therapy <ul style="list-style-type: none"> ▶ High-dose cyclophosphamide ± etoposide⁴ ▶ Oral etoposide^{5,6} ▶ TMZ^{7,8} • TMZ/irinotecan/bevacizumab^{9,10} 	<ul style="list-style-type: none"> • Consider high-dose systemic therapy with autologous stem cell reinfusion¹¹ in patients who achieve a CR with conventional doses of systemic therapy or have no residual disease after re-resection • Vismodegib (for mutations in the sonic hedgehog (SHH) pathway and if prior systemic therapy)¹²

FOOTNOTES

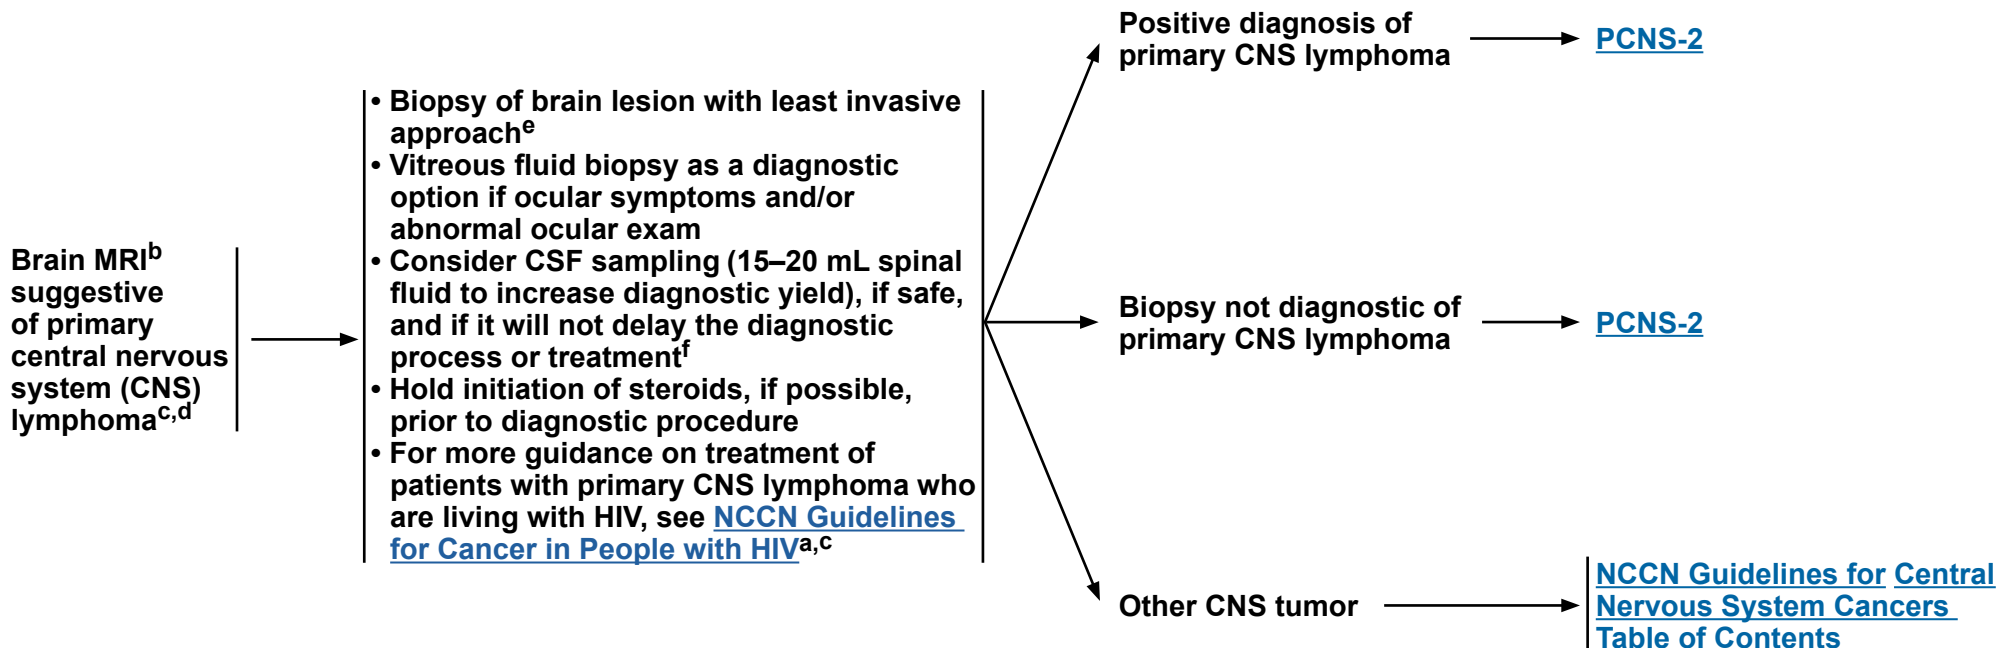

^a Omission of vincristine during radiotherapy phase of therapy or dose modification may be required for adults because they do not tolerate this regimen as well. Data supporting vincristine's use have been found in pediatric trials only. Patients should be monitored closely for neurologic toxicity with periodic exams.

^b [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

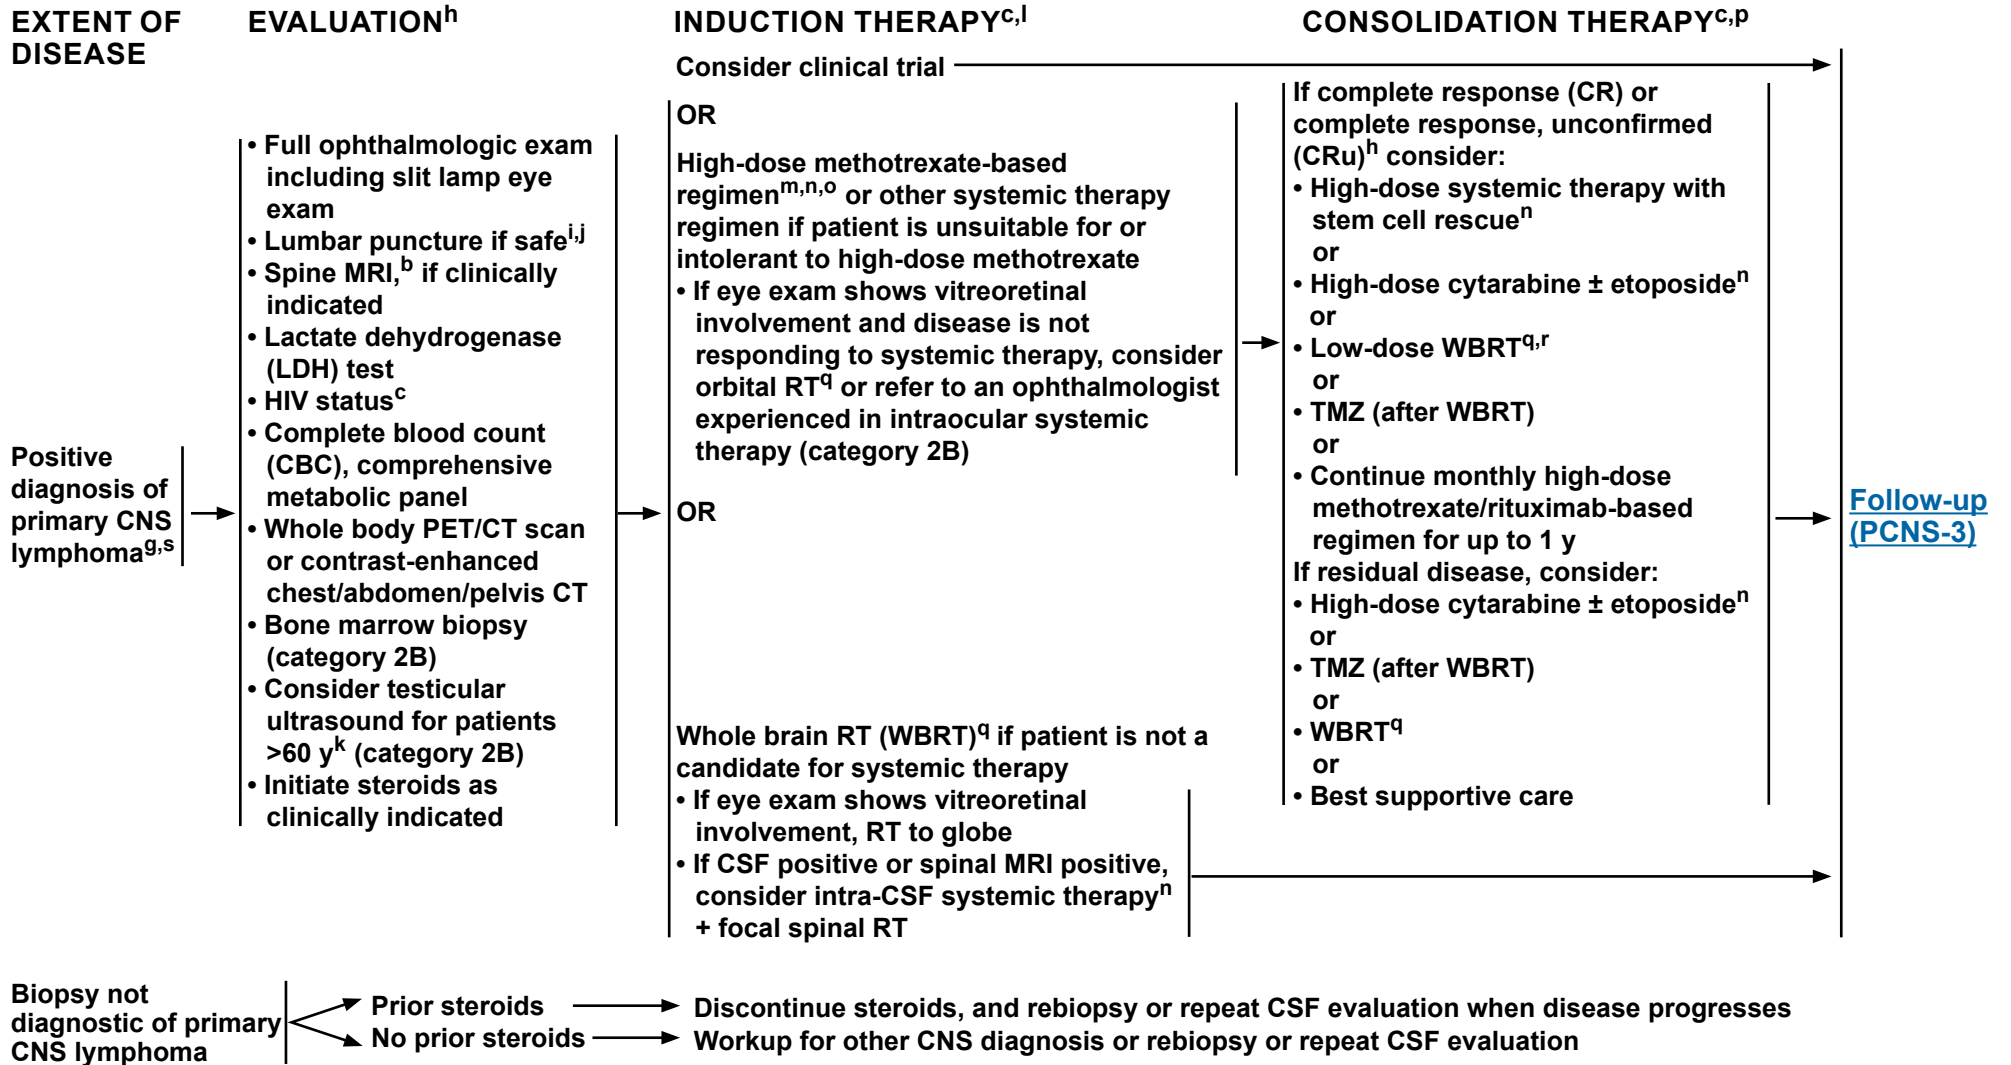

^c If patient is HIV positive, antiretroviral (ARV) therapy should be part of their treatment. ARVs can be administered safely with systemic therapy, but consultation with an HIV specialist or pharmacist is important to optimize compatibility. See [NCCN Guidelines for Cancer in People with HIV](#).

^d Includes primary CNS lymphoma of the brain, spine, CSF, and leptomeninges. For lymphoma with primary tumor outside the CNS or involving only the eye, see [NCCN Guidelines for B-Cell Lymphomas, Diffuse Large B-Cell Lymphoma](#).

^e If stereotactic biopsy is not available refer to a specialized center.

^f Brain biopsy is recommended as the primary procedure to obtain diagnosis. CSF analysis should include flow cytometry, CSF cytology, cell count, and possibly gene rearrangements, specifically the *IGH* heavy chain rearrangement. Polymerase chain reaction (PCR) of *MYD88* in the CSF is helpful.

Note: All recommendations are category 2A unless otherwise indicated.

[Footnotes \(PCNS-2A\)](#)

Note: All recommendations are category 2A unless otherwise indicated.

FOOTNOTES

^b [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^c If patient is HIV positive, ARV therapy should be part of their treatment. ARVs can be administered safely with systemic therapy but consultation with an HIV specialist or pharmacist is important to optimize compatibility. See [NCCN Guidelines for Cancer in People with HIV](#).

^g May institute primary therapy and workup simultaneously.

^h CRu refers to no enhancement, any steroids, normal eye examination and negative CSF, or minimal contrast abnormality, any steroids, minor retinal pigment epithelium, and negative CSF (Abrey LE, et al. J Clin Oncol 2005;23:5034-5043).

ⁱ CSF analysis should include flow cytometry and CSF cytology, and may consider gene rearrangements.

^j Caution is indicated in patients who are anticoagulated, thrombocytopenic, or who have a bulky intracranial mass.

^k Recommend regular testicular exams. If PET/CT scan is negative, then there is no need for testicular ultrasound.

^l A low KPS should not be a reason to withhold systemic therapy. KPS may improve dramatically after treatment.

^m Dose adjusted for glomerular filtration rate (GFR) if dosing at 8 g/m².

ⁿ [Primary CNS Lymphoma Systemic Therapy \(PCNS-A\)](#).

^o If CSF positive or spinal MRI positive, consider alternative systemic therapy regimens and/or intra-CSF systemic therapy (category 2B), especially for patients who cannot tolerate systemic methotrexate ≥ 3.5 g/m².

^p Due to a lack of strong evidence, it is not clear if consolidation is needed and which consolidation regimen provides the most benefit.

^q [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^r WBRT may increase neurotoxicity, especially in patients >60 y.

^s Includes primary CNS lymphoma of the brain, spine, CSF, and leptomeninges.

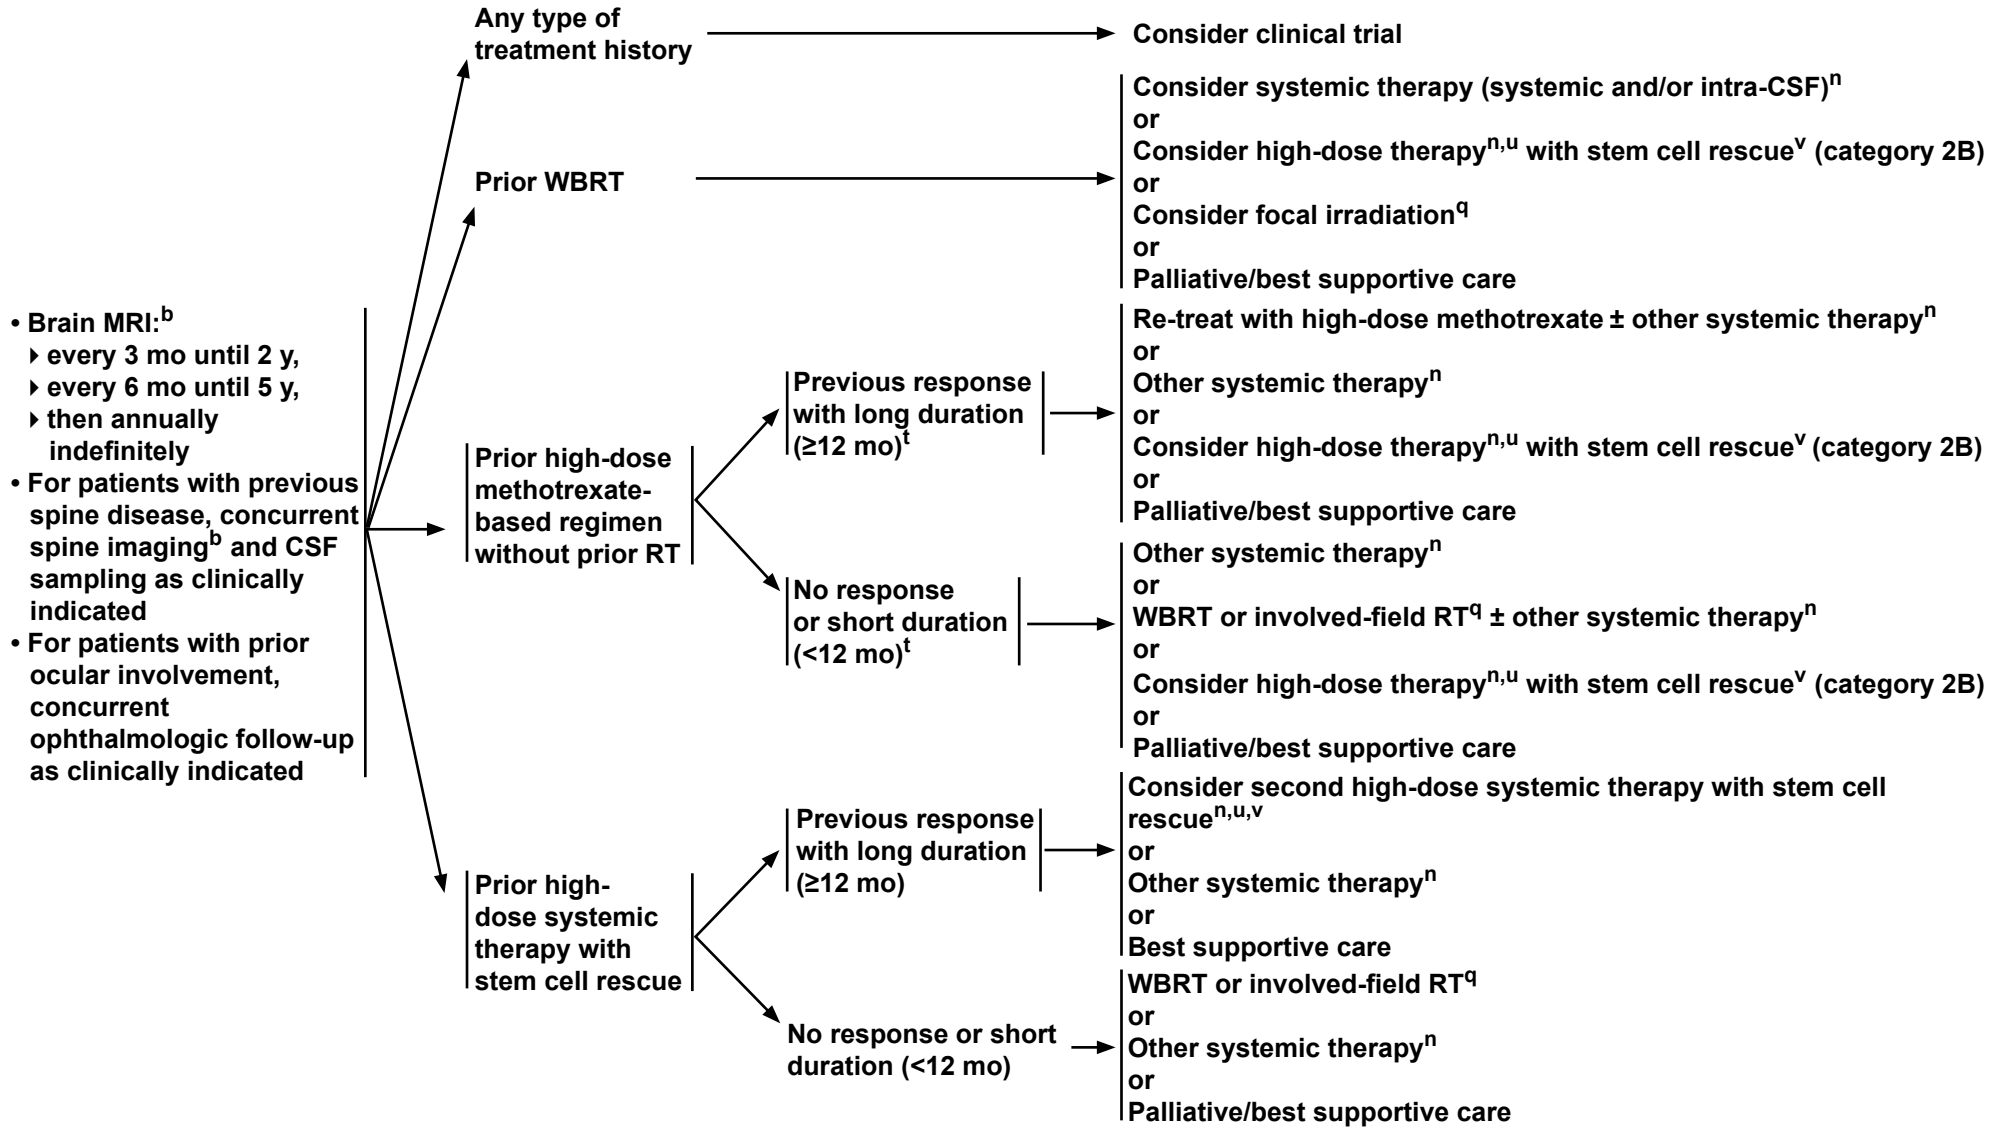

Note: All recommendations are category 2A unless otherwise indicated.

FOLLOW-UP

RELAPSED OR REFRACTORY PRIMARY CNS LYMPHOMA

TREATMENT^c

- Brain MRI:^b
 - ▶ every 3 mo until 2 y,
 - ▶ every 6 mo until 5 y,
 - ▶ then annually indefinitely
- For patients with previous spine disease, concurrent spine imaging^b and CSF sampling as clinically indicated
- For patients with prior ocular involvement, concurrent ophthalmologic follow-up as clinically indicated

Note: All recommendations are category 2A unless otherwise indicated.

[Footnotes \(PCNS-3A\)](#)

PRESENTATION^a

Radiographic diagnosis by brain MRI:

- Dural-based mass
- Homogeneously contrast-enhancing
- Dural tail
- CSF cleft

Meningioma by radiographic criteria or Possible meningioma:

- Consider resection
- Consider octreotide scan or DOTATATE PET/CT or PET/MRI scan if diagnostic doubt exists

TREATMENT^b

- Observe (preferred for small asymptomatic tumors; not generally recommended for symptomatic tumors)^c
- Consider clinical trial (for cases that are not surgically accessible but for which treatment with RT and/or systemic therapy is considered)

or

Surgery^{d,e} (if accessible)^f

or

RT^f

ADJUVANT TREATMENT

Consider RT^f depending on factors in footnote "b". In general, postoperative management depends on grade,^g extent of resection, and symptoms, as follows:

- Grade 1: observation or consider RT (for symptomatic patients)
- Grade 2 with complete resection: consider RT
- Grade 2 with incomplete resection: RT or observation in select cases (eg, low PS)
- Grade 3: RT

Follow-up (MENI-2)

^a Multidisciplinary input for treatment planning if feasible. See [NCCN Guidelines for Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic](#).

^b Treatment selection should be based on assessment of a variety of inter-related factors, including patient features (eg, age, performance score, comorbidities, treatment preferences), tumor features (eg, size, grade, growth rate, location [proximity to critical structures], potential for causing neurologic consequences if untreated, presence and severity of symptoms), and treatment-related factors (eg, potential for neurologic consequences from surgery/RT, likelihood of complete resection and/or complete irradiation with SRS, treatability of tumor if it progresses, available surgical or radiation oncology expertise and resources). The decision to administer RT after surgery also depends on the extent of resection achieved. Multidisciplinary input for treatment planning is recommended.

^c For asymptomatic meningiomas, observation is preferred for small tumors, with a suggested cutoff of ≤3 cm. Active treatment with surgery and/or RT is recommended in patients with one or more tumor- and/or treatment-related risk factors, such as proximity to the optic nerve.

^d Postoperative brain MRI within 48 hours after surgery.

^e [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^f [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^g WHO grade 1 = Benign meningioma; WHO grade 2 = Atypical meningioma; WHO grade 3 = Malignant (anaplastic) meningioma.

Note: All recommendations are category 2A unless otherwise indicated.

FOLLOW-UP^h

RECURRENCE/PROGRESSION

TREATMENT

WHO grade 1 and 2^{e,i}
or unresected meningiomas:
Brain MRI^{d,e} at 3, 6, and 12 mo,
then every 6–12 mo for 5 y,
then every 1–3 y as clinically
indicated

WHO grade 3^{e,i} meningiomas:
Brain MRI^{d,e} every 2–4 mo for
3 y, then every 3–6 mo

^d Postoperative brain MRI within 48 hours after surgery.

^e [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^f [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^h Consider less frequent follow-up after 5–10 years.

ⁱ More frequent imaging may be required for meningiomas that are treated for recurrence or with systemic therapy.

^j Consider use of additional imaging (octreotide scan or DOTATATE PET/CT or PET/MRI scan).

^k [Meningiomas Systemic Therapy \(MENI-A\)](#).

Note: All recommendations are category 2A unless otherwise indicated.

MENINGIOMAS: SYSTEMIC THERAPY

Preferred Regimens	Other Recommended Regimens	Useful in Certain Circumstances
<ul style="list-style-type: none"> • None 	<ul style="list-style-type: none"> • Sunitinib (category 2B)¹ • Bevacizumab^{a,b,2,3,4} • Bevacizumab^{a,b} + everolimus (category 2B)⁵ 	<ul style="list-style-type: none"> • Somatostatin analogue (category 2B)⁶ • Somatostatin analogue + everolimus⁷

FOOTNOTES

^a Patients who have evidence of radiographic progression may benefit from continuation of bevacizumab to prevent rapid neurologic deterioration.

^b An FDA-approved biosimilar is an appropriate substitute for bevacizumab.

CLINICAL PRESENTATION^a

WORKUP

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^b Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^c "Limited" brain metastases defines a group of patients for whom SRS is equally effective and offers significant cognitive protection compared with WBRT. The definition of "limited" brain metastases in terms of number of metastases or total intracranial disease volume is evolving and may depend on the specific clinical situation (Yamamoto M, et al. Lancet Oncol 2014;15:387-395).

^d [Principles of Brain Tumor Surgery \(BRAIN-B\)](#).

^e For secondary CNS lymphoma, treatment may include systemic treatment, WBRT or focal RT, or a combination.

^f The decision to resect a tumor may depend on the need to establish histologic diagnosis, the size of the lesion, its location, and institutional expertise. For example, smaller (<2 cm), deep, asymptomatic lesions may be considered for treatment with SRS versus larger (>2 cm), symptomatic lesions that may be more appropriate for surgery (Ewend MG, et al. J Natl Compr Cancer Netw 2008;6:505-513).

Note: All recommendations are category 2A unless otherwise indicated.

CLINICAL PRESENTATION

TREATMENT^{g,h}

^e For secondary CNS lymphoma, treatment may include systemic treatment, WBRT or focal RT, or a combination.

^g If an active agent exists (eg, cytotoxic, targeted, immune modulating), trial of systemic therapy with good CNS penetration may be considered in select patients (eg, for patients with small asymptomatic brain metastases from melanoma or *ALK* rearrangement-positive non-small cell lung cancer [NSCLC] or *EGFR*-mutated NSCLC); it is reasonable to hold on treating with radiation to see if systemic therapy can control the brain metastases. Consultation with a radiation oncologist and close MRI surveillance is strongly recommended. There are no data from prospective clinical trials comparing the two strategies to assess what the impact of delayed radiation would be in terms of survival or in delay of neurologic deficit development.

^h [Brain Metastases Systemic Therapy \(BRAIN METS-A\)](#).

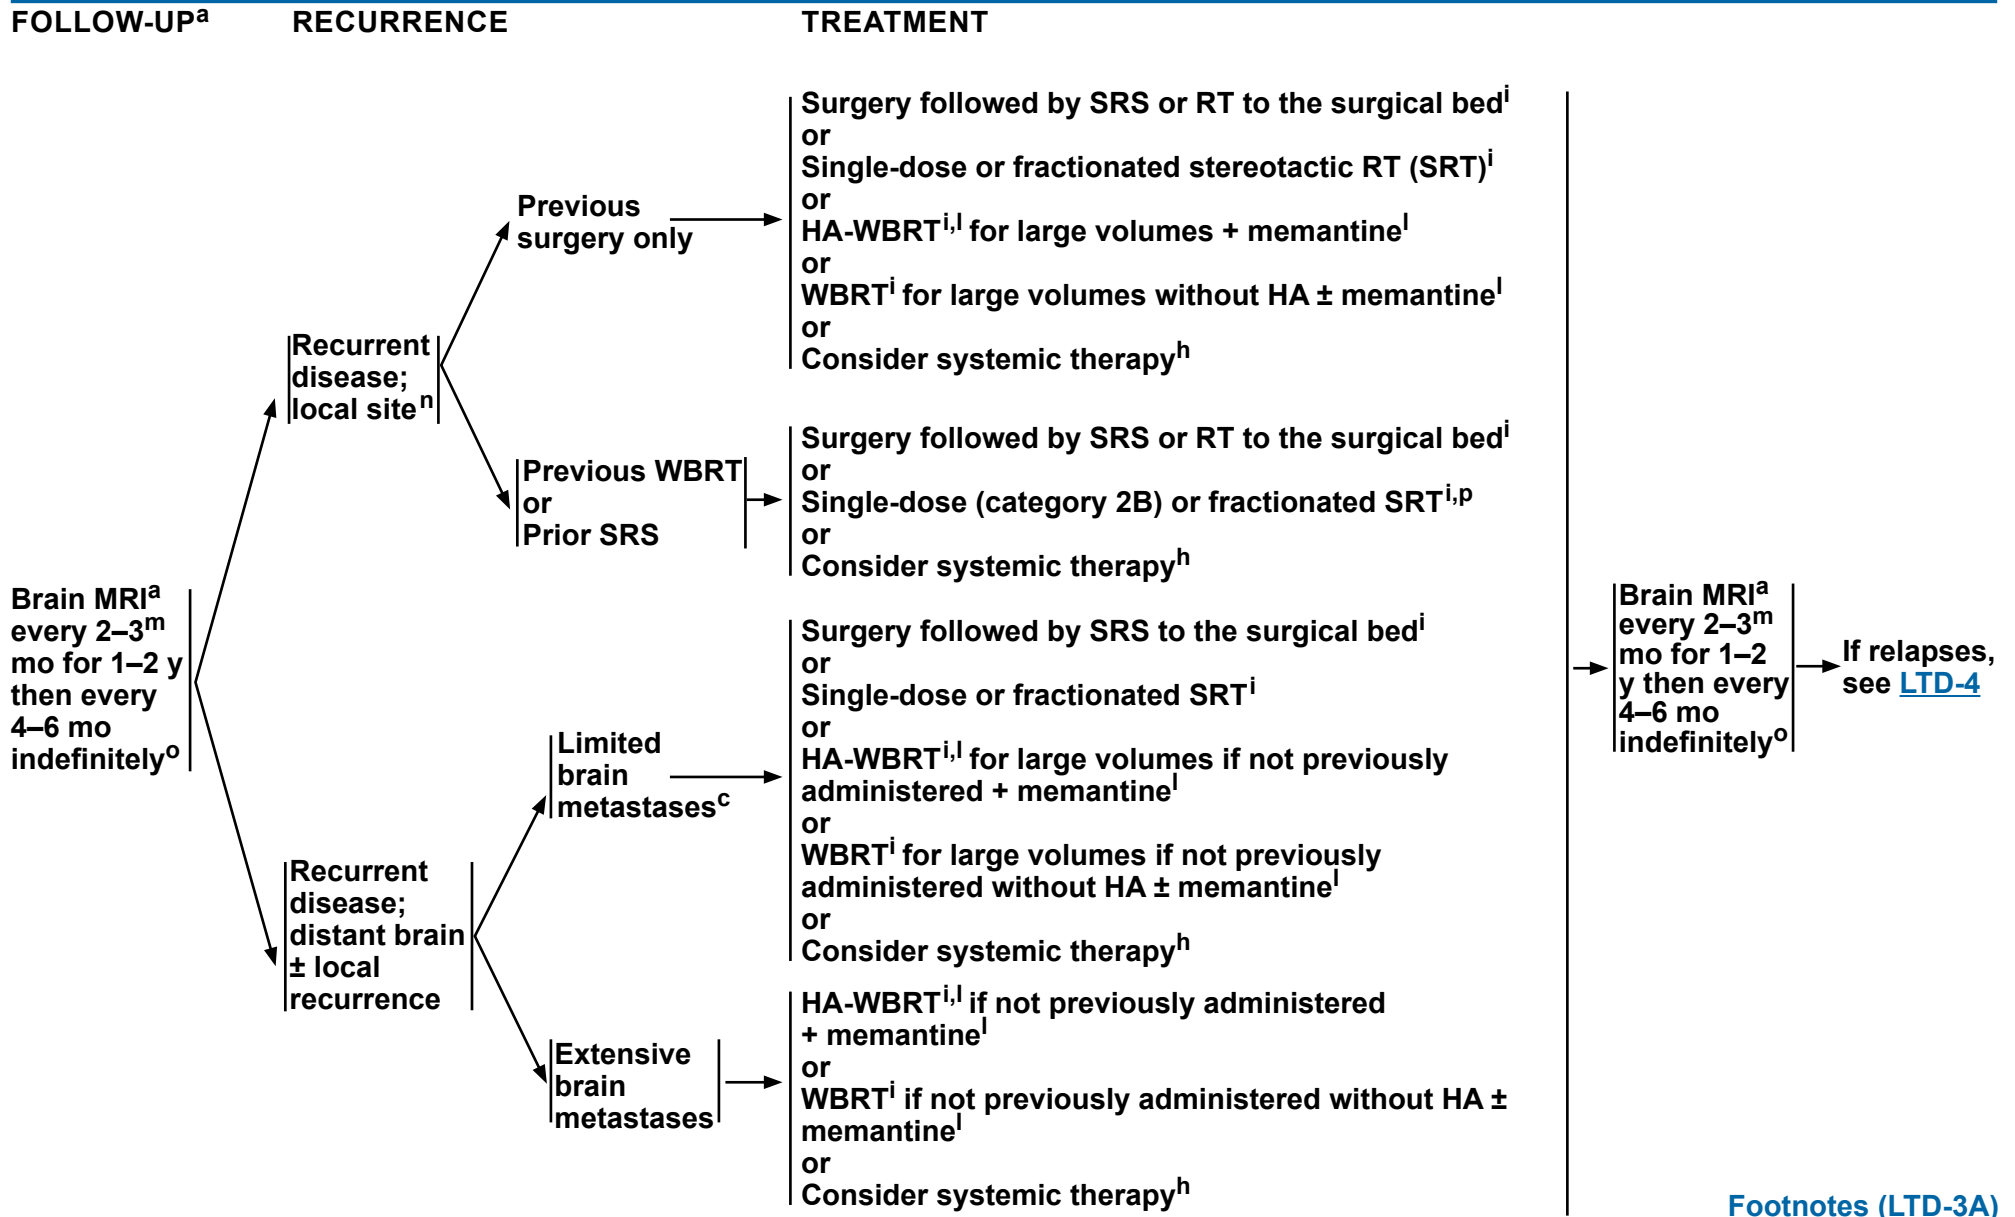

ⁱ [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^j SRS is preferred when safe, especially for low tumor volume, to both the resection cavity and any other non-resected brain metastases. WBRT is generally not recommended but may be appropriate in some rare clinical circumstances.

^k For brain metastases not managed with resection, SRS + WBRT is generally not recommended, as the addition of WBRT to SRS does not improve survival and can be associated with greater cognitive decline and poorer quality of life (QOL) (Brown PD, et al. *JAMA* 2016;316:401-409). However, the combination of SRS and WBRT may be appropriate in carefully selected clinical circumstances (eg, WBRT is already being offered for extensive brain metastases and an SRS boost is considered for a large lesion or radioresistant histology for the goal of improving local control) (Andrews DW, et al. *Lancet* 2004;363.9422:1665-1672).

^l Brain metastases not within 5 mm of the hippocampi; life expectancy of at least 4 months. In patients without brain metastases within 5 mm of the hippocampi, HA-WBRT + memantine was superior to WBRT + memantine in terms of cognitive preservation and patient-reported QOL (Brown PD, et al. *J Clin Oncol* 2020;38:1019-1029 and Brown PD, et al. *Neuro Oncol* 2013;15:1429-1437).

Note: All recommendations are category 2A unless otherwise indicated.

FOOTNOTES

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^c "Limited" brain metastases defines a group of patients for whom SRS is equally effective and offers significant cognitive protection compared with WBRT. The definition of "limited" brain metastases in terms of number of metastases or total intracranial disease volume is evolving and may depend on the specific clinical situation. (Yamamoto M, et al. *Lancet Oncol* 2014;15:387-395.)

^h [Brain Metastases Systemic Therapy \(BRAIN METS-A\)](#).

ⁱ [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^l Brain metastases not within 5 mm of the hippocampi; life expectancy of at least 4 months. In patients without brain metastases within 5 mm of the hippocampi, HA-WBRT + memantine was superior to WBRT + memantine in terms of cognitive preservation and patient-reported quality of life (Brown PD, et al. *J Clin Oncol* 2020;38:1019-1029 and Brown PD, et al. *Neuro Oncol* 2013;15:1429-1437).

^m MRI every 2 months (instead of 3 mo) for those patients treated with SRS alone.

ⁿ After SRS, imaging changes may reflect treatment changes or tumor progression. Consider advanced MRI imaging, multidisciplinary input, or observation with early repeat imaging. When diagnosis remains unclear, consider tissue sampling.

^o Imaging to evaluate emergent signs/symptoms is appropriate at any time.

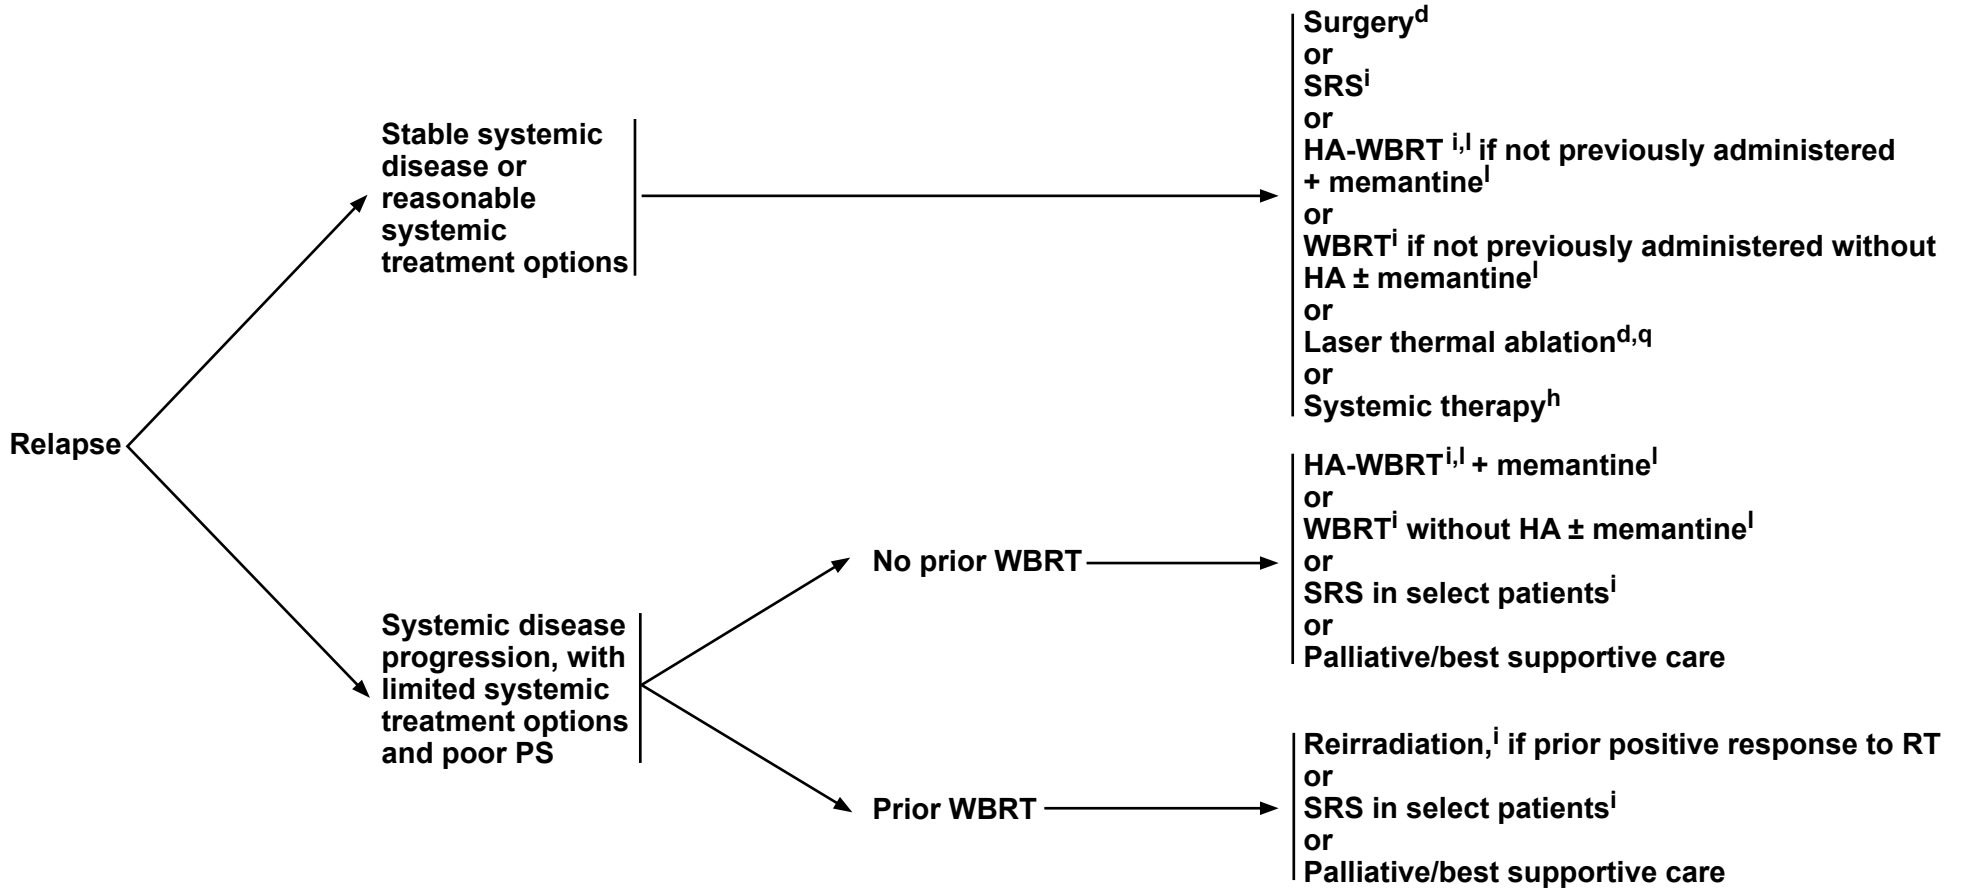

^p If patient had previous SRS with a good response >6 mo, then reconsider SRS if imaging supports active tumor and not necrosis.

Note: All recommendations are category 2A unless otherwise indicated.

RECURRENCE

TREATMENT

^d [Principles of Brain Tumor Surgery \(BRAIN-B\)](#).

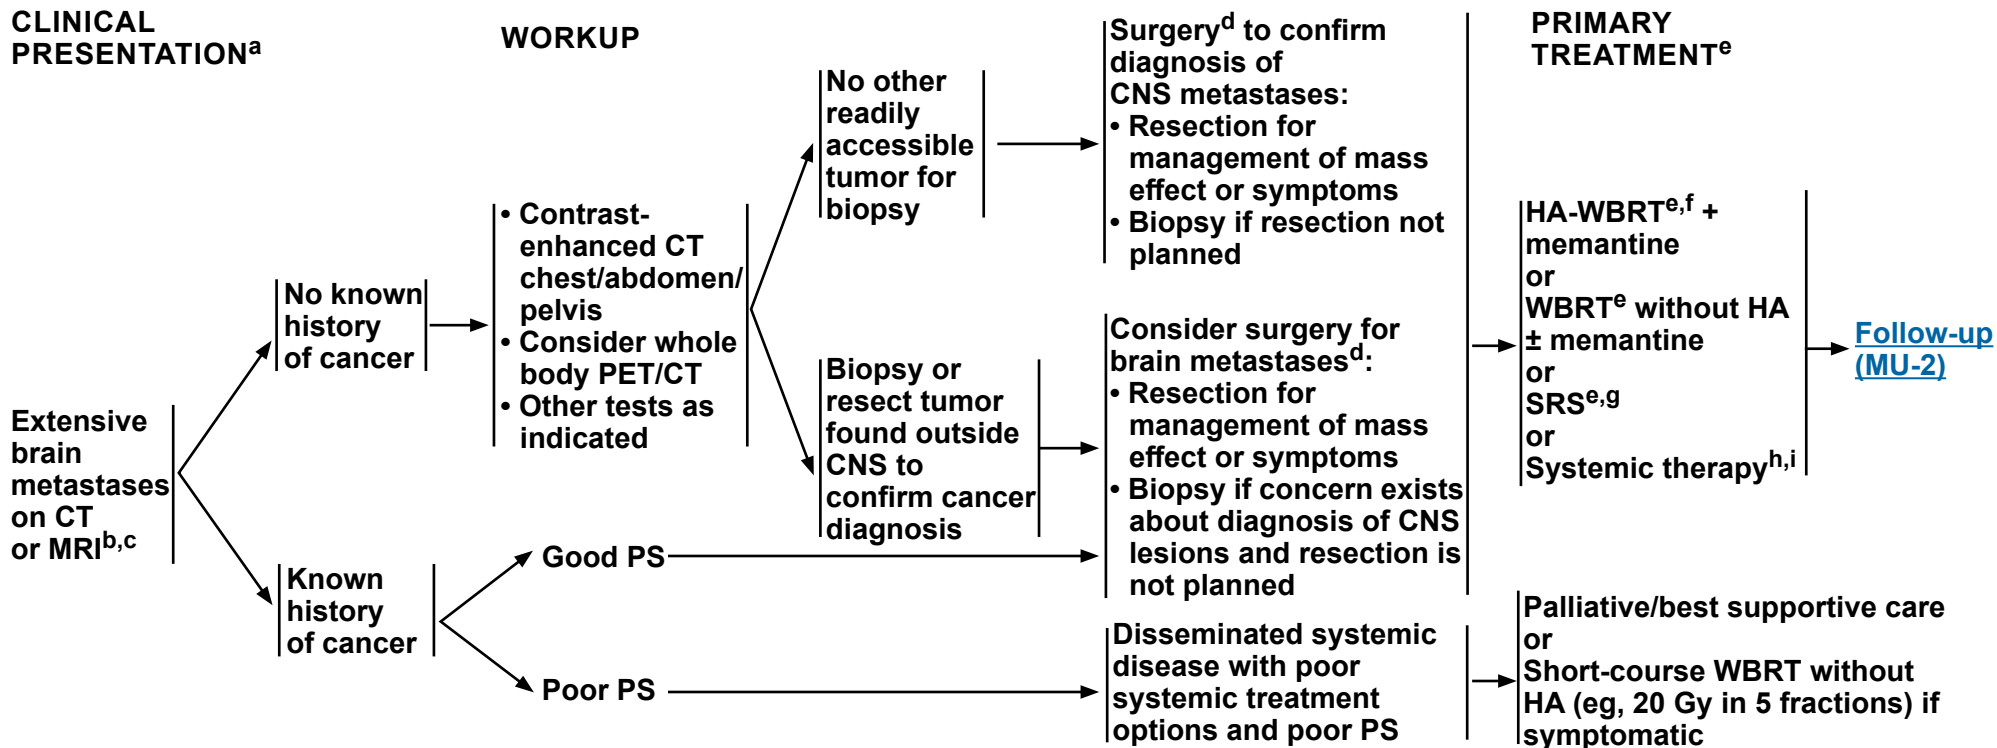

^h [Brain Metastases Systemic Therapy \(BRAIN METS-A\)](#).

ⁱ [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^l Brain metastases not within 5 mm of the hippocampi; life expectancy of at least 4 months. In patients without brain metastases within 5 mm of the hippocampi, HA-WBRT + memantine was superior to WBRT + memantine in terms of cognitive preservation and patient-reported QOL (Brown PD, et al. J Clin Oncol 2020;38:1019-1029 and Brown PD, et al. Neuro Oncol 2013;15:1429-1437).

^q This option is for patients who are not considered surgical candidates (Ahluwalia M, et al. J Neurosurg 2018;130:804-811 and Hernandez RN, et al. Neurosurgery 2019;85:900-904).

Note: All recommendations are category 2A unless otherwise indicated.

^a [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^b Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^c Includes all cases that do not fit the definition of "limited brain metastases" on [LTD-1](#).

^d [Principles of Brain Tumor Surgery \(BRAIN-B\)](#).

^e [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^f Brain metastases not within 5 mm of the hippocampi; KPS ≥70; life expectancy of at least 4 months; no leptomeningeal disease. In patients without brain metastases within 5 mm of the hippocampi, HA-WBRT + memantine was superior to WBRT + memantine in terms of cognitive preservation and patient-reported QOL (Brown PD, et al. J Clin Oncol 2020;38:1019-1029 and Brown PD, et al. Neuro Oncol 2013;15:1429-1437).

^g SRS can be considered for patients with good performance and low overall tumor volume and/or radioresistant tumors such as melanoma (Yamamoto M, et al. Lancet Oncol 2014;15:387-395).

^h If an active agent exists (eg, cytotoxic, targeted, immune modulating), trial of systemic therapy with good CNS penetration may be considered in select patients (eg, for patients with small asymptomatic brain metastases from melanoma or ALK rearrangement-positive NSCLC or EGFR-mutated NSCLC); it is reasonable to hold on treating with radiation to see if systemic therapy can control the brain metastases. Consultation with a radiation oncologist and close MRI surveillance is strongly recommended. There are no data from prospective clinical trials comparing the two strategies to assess what the impact of delayed radiation would be in terms of survival or in delay of neurologic deficit development.

ⁱ [Brain Metastases Systemic Therapy \(BRAIN METS-A\)](#).

^j Imaging to evaluate emergent signs/symptoms is appropriate at any time.

^k After SRS, recurrence on MRI can be confounded by treatment effects; consider tumor tissue sampling if there is a high index of suspicion of recurrence.

Note: All recommendations are category 2A unless otherwise indicated.

BRAIN METASTASES^a: SYSTEMIC THERAPY

- **Tumor Agnostic^b**
 - ▶ ***NTRK* gene fusion tumors**
 - ◊ Preferred Regimens
 - Larotrectinib¹
 - Entrectinib²
 - Repotrectinib³
 - ◊ Other Recommended Regimen
 - TMZ 5/28 Schedule
 - ▶ **MSI-H/dMMR or TMB-H (≥10 mut/Mb) tumors for isolated brain metastases**
 - ◊ Preferred Regimen
 - Pembrolizumab (category 2B)^{4,5}
- **Breast Cancer^c**
 - ▶ **HER2 positive**
 - ◊ Preferred Regimens
 - Tucatinib + trastuzumab^d + capecitabine (category 1)
(if previously treated with 1 or more anti-HER2–based regimens)⁶
 - ◊ Other Recommended Regimens
 - Fam-trastuzumab deruxtecan-nxki^{7,8}
 - Ado-trastuzumab emtansine (T-DM1)⁹
 - Capecitabine + lapatinib^{10,11}
 - Capecitabine + neratinib^{12,13}
 - Pertuzumab and high-dose trastuzumab^{d,14}
 - Paclitaxel + neratinib (category 2B)¹⁵
 - ▶ **HER2 non-specific**
 - ◊ Other Recommended Regimens
 - Capecitabine¹⁶⁻²⁰
 - Cisplatin (category 2B)^{21,22}
 - Etoposide (category 2B)^{21,22}
 - Cisplatin + etoposide (category 2B)^{22,23}
 - High-dose methotrexate (category 2B)^{e,24}
- **Melanoma^c**
 - ▶ ***BRAF* V600E positive**
 - ◊ Preferred Regimens
 - Dabrafenib²⁵⁻²⁷/trametinib²⁸
 - Vemurafenib^{29,30}/cobimetinib^f (category 2B)
 - ▶ **Melanoma^c**
 - ◊ Preferred Regimen
 - Ipilimumab + nivolumab³¹⁻³³
 - ◊ Other Recommended Regimens
 - Ipilimumab³⁴
 - Nivolumab³²
 - Pembrolizumab³⁵
- **Non-Small Cell Lung Cancer (NSCLC)^c**
 - ▶ ***KRAS* G12C mutation**
 - ◊ Adagrasib^{36,37}
 - ◊ Sotorasib (category 2B)³⁸
 - ▶ **EGFR-sensitizing mutation positive**
 - ◊ Preferred Regimen
 - Osimertinib³⁹⁻⁴¹
 - ◊ Other Recommended Regimens
 - Pulsatile erlotinib⁴²⁻⁴⁴
 - Afatinib (category 2B)⁴⁵
 - Gefitinib (category 2B)^{46,47}
 - ▶ ***MET* exon 14 mutated**
 - ◊ Other Recommended Regimens
 - Capmatinib⁴⁸
 - Tepotinib^{49,50}
 - ▶ ***RET* fusion positive**
 - ◊ Selpercatinib⁵¹
 - ▶ ***ALK* rearrangement positive**
 - ◊ Preferred Regimens
 - Brigatinib^{52,53}
 - Lorlatinib⁵⁴
 - Alectinib^{55,56}
 - Ceritinib⁵⁷
 - ▶ ***ALK* rearrangement positive or *ROS1* positive**
 - ◊ Crizotinib (category 2B)⁵⁸
 - ▶ **PD-L1 positive**
 - ◊ Other Recommended Regimens
 - Pembrolizumab^{35,59} (tumor proportion score [TPS] ≥1%)
 - Nivolumab⁶⁰⁻⁶² (TPS ≥1%)
- **Small Cell Lung Cancer^c**
 - ◊ Topotecan (category 2B)
- **Lymphoma^c**
 - ◊ High-dose methotrexate⁶³
 - ◊ BTK inhibitor (eg, ibrutinib)⁶⁴
- **Renal Cell Carcinoma^c**
 - ▶ Cabozantinib⁶⁵
 - ▶ Belzutifan (category 2B)⁶⁶ (for VHL-associated RCC)

Note: All recommendations are category 2A unless otherwise indicated.

BRAIN METASTASES: SYSTEMIC THERAPY

FOOTNOTES

- ^a If an active agent exists (eg, cytotoxic, targeted, immune modulating), trial of systemic therapy with good CNS penetration may be considered in select patients (eg, for patients with small asymptomatic brain metastases it is reasonable to hold on treating with radiation to see if systemic therapy can control the brain metastases). Consultation with a radiation oncologist and close MRI surveillance is strongly recommended. There are no data from prospective clinical trials comparing the two strategies to assess what the impact of delayed radiation would be in terms of survival or in delay of neurologic deficit development.
- ^b See the appropriate NCCN treatment guidelines for systemic therapy recommendations for newly diagnosed brain metastases for any cancers not listed here.
- ^c Use active agents against primary tumor.
- ^d An FDA-approved biosimilar is an appropriate substitute for trastuzumab.
- ^e Consider glucarpidase (carboxypeptidase G2) for prolonged methotrexate clearance due to methotrexate-induced renal toxicity. Ramsey LB, Balis FM, O'Brien MM, et al. Consensus guideline for use of glucarpidase in patients with high-dose methotrexate induced acute kidney injury and delayed methotrexate clearance. *Oncologist* 2018;23:52-61.
- ^f Although there are no published prospective studies on the combination of vemurafenib and cobimetinib for melanoma patients with brain metastases, there is high-quality evidence that for melanoma with distant metastasis, combination therapy with vemurafenib and cobimetinib is associated with improved outcomes and safety compared with single-agent vemurafenib.

Note: All recommendations are category 2A unless otherwise indicated.

^a Based on multidisciplinary review for treatment planning, once pathology is available. See [Principles of Brain and Spine Tumor Management \(BRAIN-D\)](#).

^b [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^c Caution is indicated in patients who are anticoagulated, thrombocytopenic, or who have a bulky intra-cranial mass.

^d CSF analysis should include: a cell count, differential, glucose, and protein. For solid malignancies, order cytopathology. When available, assessment of circulating tumor DNA (ctDNA) or circulating tumor cells (CTCs) increases sensitivity of tumor cell detection and assessment of response to treatment. For hematologic malignancies, use flow cytometry.

^e For patients receiving immunotherapy, CSF sampling rather than just MRI enhancement is suggested as evidence of leptomeningeal metastases, in order to exclude immune-related aseptic meningitis.

^f Suggestive CSF includes high white blood cell (WBC) count, low glucose, and high protein. If CSF is not positive for tumor cells, a second lumbar puncture is sometimes helpful. This is a volume-dependent test, and ideally ≥10 mL should be sent for cytologic analysis.

^g Patients with tumors that are highly sensitive to systemic therapy or targeted therapy may be treated. Patients with a good risk status who do not desire further therapy may also be treated with palliative and/or best supportive care. See [LEPT-3](#) for response assessment.

Note: All recommendations are category 2A unless otherwise indicated.

RISK STATUS

TREATMENT

- Good risk:**
- KPS ≥60
 - No major neurologic deficits
 - Minimal systemic disease
 - Reasonable systemic treatment options, if needed

- Systemic therapy^h
- Intra-CSF therapy^{h,i}
 - ▶ If symptoms or imaging suggest CSF flow blockage, perform a CSF flow scan prior to starting intra-CSF therapy
 - If flow abnormalities confirmed:
 - ◊ Fractionated EBRT^j to metastatic or painful sites of obstruction and repeat CSF flow scan to see if flow abnormalities have resolved
 - or
 - ◊ High-dose methotrexate if breast cancer or lymphoma
- Radiation therapy^{j,k}
 - ▶ Consider involved-field RT (eg, partial or WBRT, skull base RT, focal spine RT) to bulky disease for focal disease control and to neurologically symptomatic or painful sites
 - ▶ Consider craniospinal irradiation (CSI) for CNS and CSF disease control in select patients with or without symptoms

Assessment of response
[\(LEPT-3\)](#)

- Poor risk:^g**
- KPS <60
 - Multiple, serious, major neurologic deficits
 - Extensive systemic disease with few treatment options
 - Bulky CNS disease
 - Encephalopathy

Palliative/best supportive care and
Consider involved-field RT^j to neurologically symptomatic or painful sites for palliation (including spine and intracranial disease)

^g Patients with tumors that are highly sensitive to systemic therapy or targeted therapy may be treated. Patients with a good risk status who do not desire further therapy may also be treated with palliative and/or best supportive care. See [LEPT-3](#) for response assessment.

^h [Leptomeningeal Metastases Systemic Therapy \(LEPT-A\)](#).

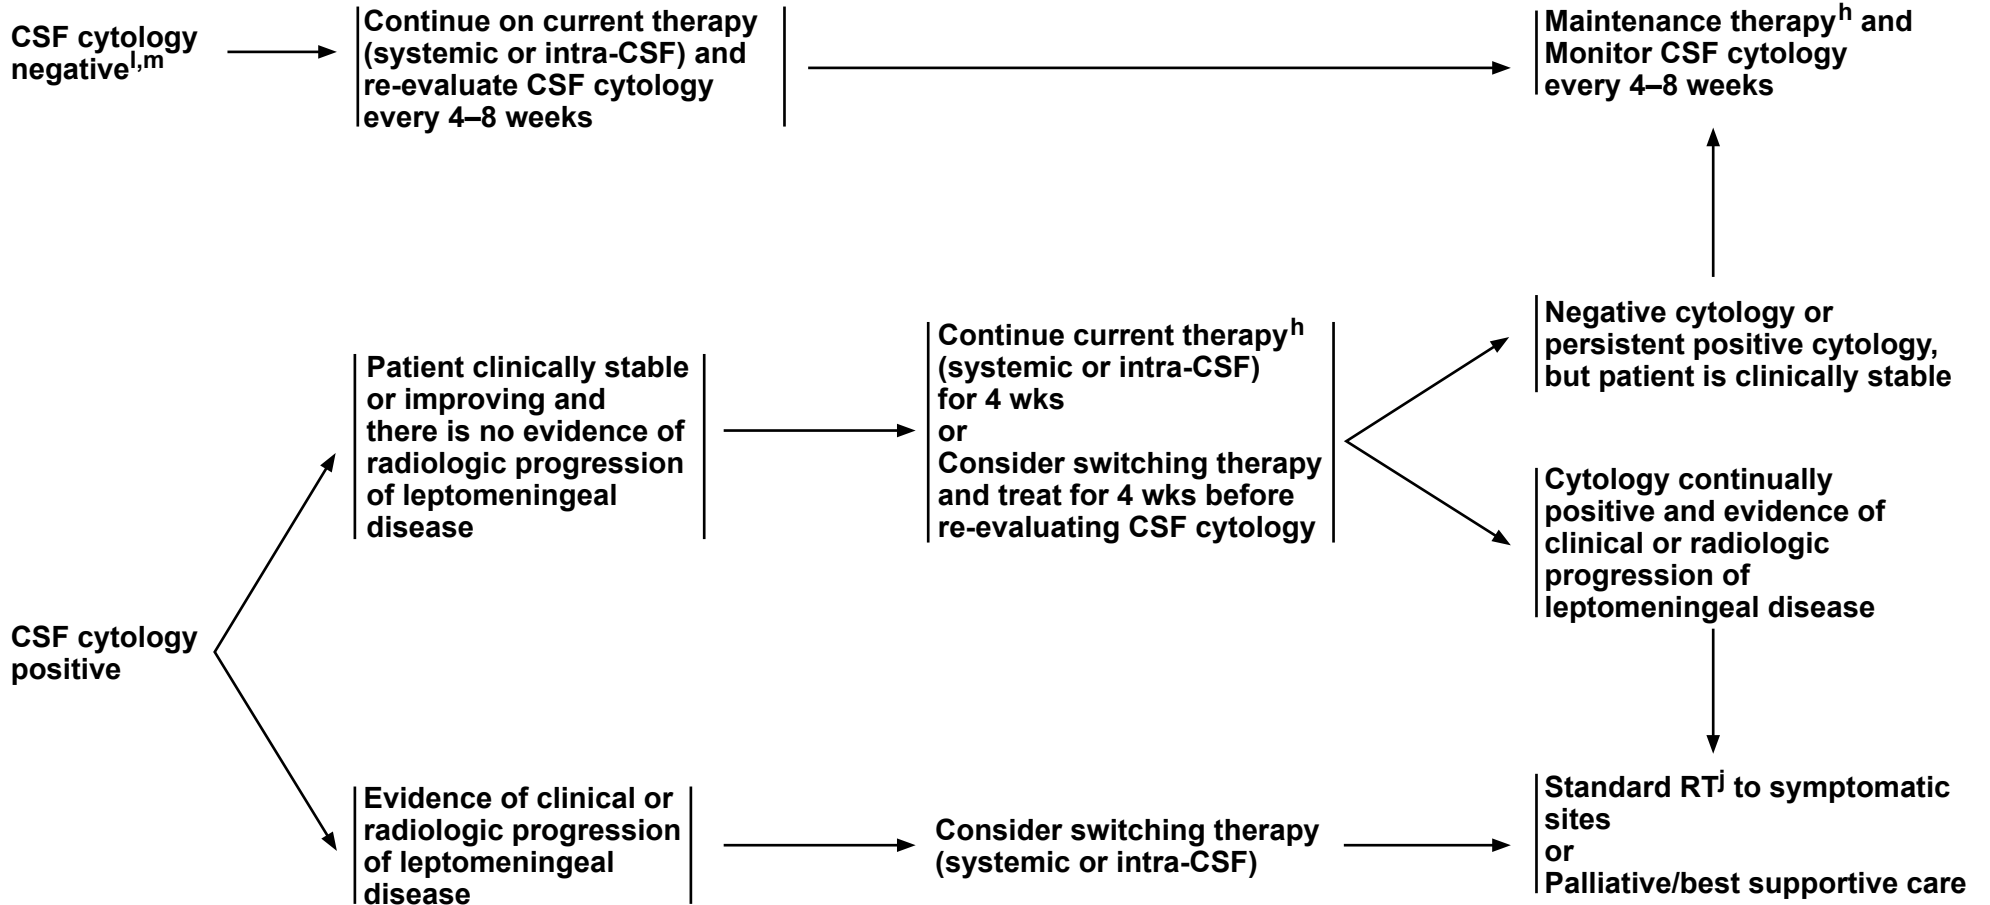

ⁱ Strongly consider Ommaya reservoir/intraventricular catheter.

^j [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^k Use of advanced modalities to minimize toxicity, including techniques in maximizing bone marrow sparing, is recommended when considering craniospinal RT (eg, protons when available [Yang JT, et al. J Clin Oncol 2022;40:3858-3867], or conformal photon-based techniques/IMRT). In addition, careful assessment and monitoring of blood counts should be performed given risk of hematologic toxicity.

Note: All recommendations are category 2A unless otherwise indicated.

TREATMENT

^h [Leptomeningeal Metastases Systemic Therapy \(LEPT-A\)](#).

^j [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^l If cytologic analysis is negative from CSF obtained from an Ommaya reservoir, then assess CSF obtained via a lumbar puncture to confirm CSF cytology is negative.

^m If CSF cytology was initially negative or new/worsening clinical signs/symptoms, then assess response with MRI of spine/brain.

Note: All recommendations are category 2A unless otherwise indicated.

LEPTOMENINGEAL METASTASES: SYSTEMIC THERAPY

• Treatment

▶ Systemic therapy specific to primary cancer type; emphasizing drugs with good CNS penetration

▶ Intra-CSF therapy¹

◊ Other Recommended Regimens

- Thiotepa²
- Topotecan³
- Etoposide⁴
- Cytarabine⁵⁻⁸
- Methotrexate^{7,9-11}

▶ Lymphoma

◊ Intra-CSF therapy

- Rituximab^{a,6}

◊ High-dose methotrexate^{b,12}

▶ Breast cancer

◊ Other Recommended Regimens

– Intra-CSF therapy

- Methotrexate^{7,9,10}
- Trastuzumab^c (HER2 positive)¹³

◊ Useful in Certain Circumstances

- High-dose methotrexate^{b,14,15,16}

▶ NSCLC

◊ Preferred Regimens

- Osimertinib *EGFR* mutation positive^{17,18,19}

◊ Other Recommended Regimens

- Weekly pulse erlotinib *EGFR* exon 19 deletion or exon 21 L858R mutation (category 2B)²⁰
- Intrathecal pemetrexed *EGFR* mutation positive^{21,22}

◊ Useful in Certain Circumstances

- Tepotinib²³ (*MET* exon 14 mutated)

▶ Melanoma

◊ Useful in Certain Circumstances

- IT and IV nivolumab (category 2B)²⁴

^a An FDA-approved biosimilar is an appropriate substitute for rituximab.

^b Consider glucarpidase (carboxypeptidase G2) for prolonged methotrexate clearance due to methotrexate-induced renal toxicity. Ramsey LB, Balis FM, O'Brien MM, et al. Consensus guideline for use of glucarpidase in patients with high-dose methotrexate induced acute kidney injury and delayed methotrexate clearance. *Oncologist* 2018;23:52-61.

^c An FDA-approved biosimilar is an appropriate substitute for trastuzumab.

Note: All recommendations are category 2A unless otherwise indicated.

PRESENTATION

Patient diagnosed with cancer
or patient with newly discovered abnormality
suspicious for spine metastasis

Asymptomatic
(incidental finding)

Symptomatic:
• Severe, new, or
progressive pain
or neurologic
symptoms or
myelopathy

WORKUP

- Systemic imaging (ie, contrast-enhanced chest/abdomen/pelvis CT or whole body PET/CT, bone scan as indicated for metastatic workup)
- Biopsy^a if it alters management

Spinal MRI^{b,c,d}
(urgent in the event of
neurologic symptoms)

TREATMENT

- Observation
Spine MRI^d in 6–8 weeks, then every 2–3 months until the nature of the lesion is established
- Surgery/focal RT^e or systemic therapy^f are options for patients with asymptomatic epidural disease

No tumor

Spinal cord compression^g

No spinal cord compression^d

[SPINE-2](#)

^a Biopsy if remote history of cancer.

^b If the patient is unable to have an MRI, then a CT myelogram is recommended, which may also be useful for RT planning.

^c 15%–20% of patients have additional lesions. Highly recommend complete spine imaging.

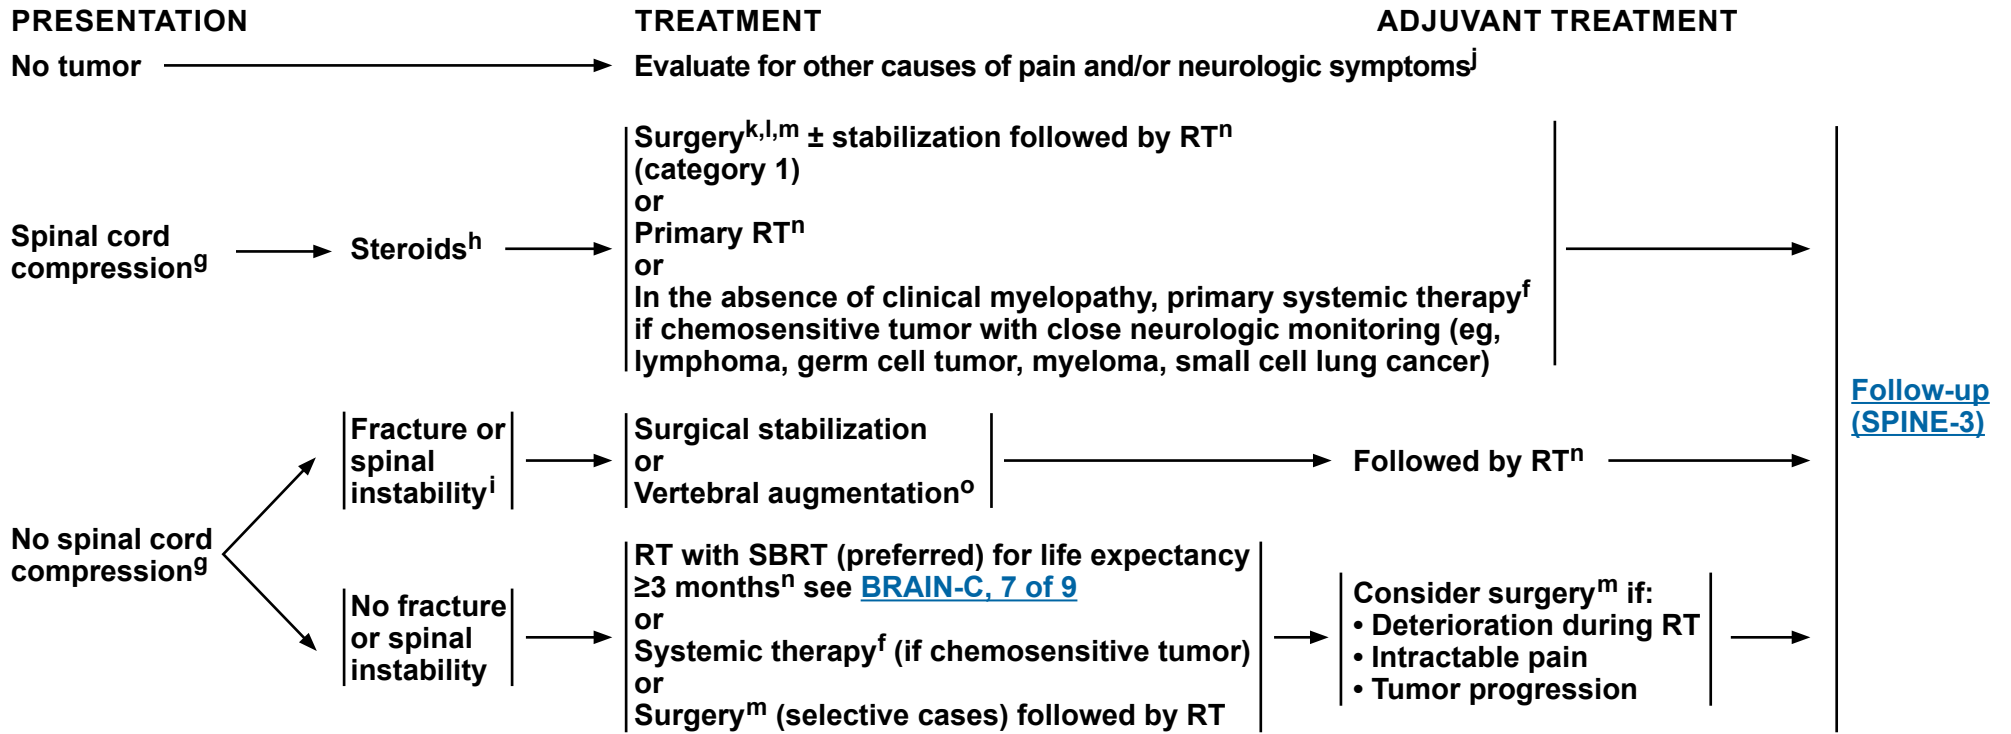

^d [Principles of Brain and Spine Tumor Imaging \(BRAIN-A\)](#).

^e [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^f Use regimen for disease-specific site.

^g Includes cauda equina syndrome.

Note: All recommendations are category 2A unless otherwise indicated.

^f Use regimen for disease-specific site.

^g Includes cauda equina syndrome.

^h The recommended minimum dose of steroids is 4 mg of dexamethasone every 6 hours, although dose of steroids may vary (10–100 mg). A randomized trial supported the use of high-dose steroids (Sorensen S, et al. Eur J Cancer 1994;30A:22-27).

ⁱ Spinal instability is grossly defined as the presence of significant kyphosis or subluxation (deformity), or of significantly retropulsed bone fragment and may be evaluated using the Spinal Instability Neoplastic Score (Versteeg AL, et al. Spine 2016;41:S231-S237).

^j Consider alternative diagnosis of leptomeningeal disease ([LEPT-1](#)).

^k Tumor resection with or without spinal stabilization. Surgery should be focused on anatomic pathology.

^l Regarding surgery, note the following:

- Category 1 evidence supports the role of surgery in patients with a solitary epidural spinal cord compression by a tumor not known to be radiosensitive and who are willing to undergo surgery (Patchell RA, et al. Lancet 2005;366:643-648).
- For surgery, patients with hematologic tumors (ie, lymphoma, myeloma, leukemia) should be excluded, life expectancy should be ≥3 mo, and the patient should not be paraplegic for >24 h.
- Surgery is especially indicated if the patient has any of the following: spinal instability, no history of cancer, rapid neurologic deterioration during RT, previous RT to site, and single-site spinal cord compression.

^m Postoperative spine MRI should be delayed by at least 2–3 weeks to avoid post-surgical artifacts. See [Principles of Brain Tumor Surgery \(BRAIN-B\)](#).

ⁿ Ablative doses of RT yield significantly higher rates of pain improvement and disease control (Sahgal A, et al. Lancet Oncol 2021;22:1023-1033 and Palma DA, et al. J Clin Oncol 2020;38:2830-2838). See [Principles of Radiation Therapy for Brain and Spinal Cord \(BRAIN-C\)](#).

^o Vertebral augmentation: vertebroplasty, kyphoplasty.

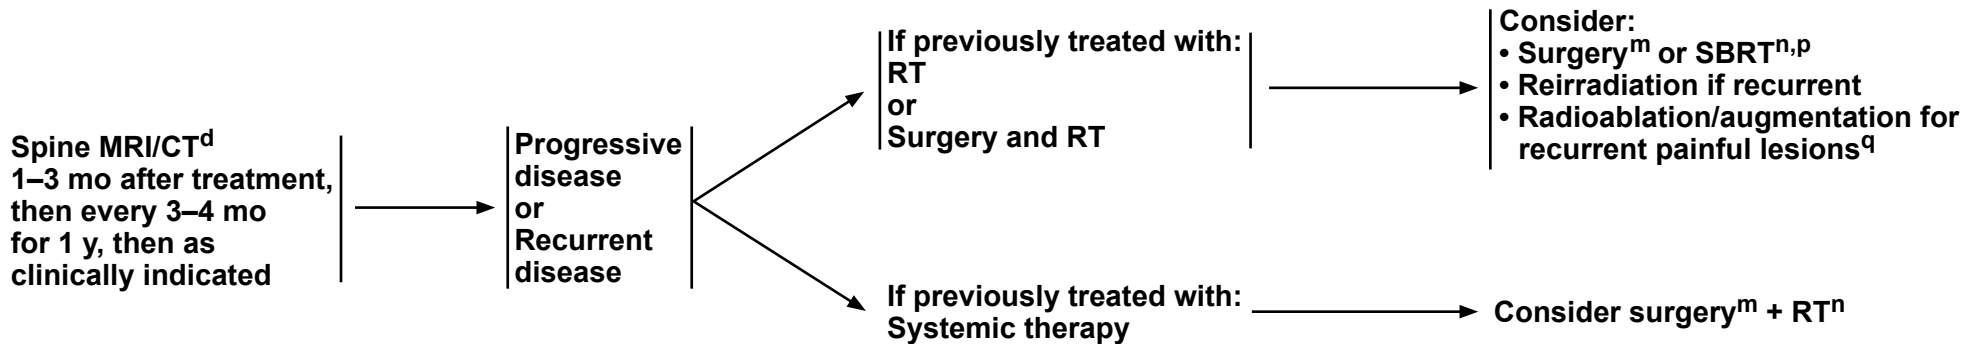

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF BRAIN AND SPINE TUMOR IMAGING¹

This is a list of imaging modalities available and used in neuro-oncology primarily to make treatment decisions. The most common use for magnetic resonance (MR) spectroscopy, MR perfusion, and PET scanning is to differentiate radiation necrosis from active tumor, as this might obviate the need for surgery or the discontinuation of an effective therapy. Imaging is always recommended to investigate emergent signs or symptoms.

- **MRI² of the brain and spine (with and without contrast):**
 - ▶ Gold standard
 - ▶ Provides a “static” picture of tumors
 - ▶ Benefits: Provides a reasonably good delineation of tumors; higher grade tumors and brain leptomeningeal metastasis usually enhance; lower grade tumors usually do not enhance
 - ▶ Limitations: Sensitive to movement, metallic objects cause artifact, implantable devices are unsafe for MRI, claustrophobia may be an issue, or renal insufficiency may occur
 - ▶ Postoperative brain MRI should be performed within 48 hours for gliomas and other brain tumors to determine extent of resection.
 - ▶ Postoperative spine MRI should be delayed by at least 2–3 weeks to avoid post-surgical artifacts.
 - ▶ Follow-up brain MRI should be performed at the frequency and intervals stated in the treatment algorithms. More frequent imaging may be done as clinically indicated by the treating physician, such as in the event of a clinical change such as development of seizures or neurologic deterioration.
- **CT of the brain and spine (with and without contrast):**
 - ▶ Should be used in patients who cannot have an MRI
 - ▶ Benefits: Claustrophobia or implantable devices are not an issue, can be done faster than an MRI
 - ▶ Limitations: Lacks resolution of MRI, especially in posterior fossa, or renal insufficiency
- **MR spectroscopy: Assess metabolites within tumors and normal tissue**
 - ▶ May be useful in differentiating tumor from radiation necrosis; may be helpful in grading tumors or assessing response
 - ▶ Area most abnormal would be the best place to target for a biopsy
 - ▶ Limitations: Tumors near vessels, air spaces, or bone. Extra time in MRI and others as noted under MRI
- **MR perfusion: Measures cerebral blood volume in tumors**
 - ▶ May be useful in differentiating grade of tumor or tumor versus radiation necrosis. Area of highest perfusion would be the best place to biopsy
 - ▶ Limitations: Tumors near vessels, air spaces, bone, small-volume lesions, or tumors in the spinal cord. Extra time in MRI and others as noted under MRI
- **Brain FDG-PET/CT scanning: Assess metabolism within tumor and normal tissue by using radiolabeled tracers**
 - ▶ May be useful in differentiating tumor from radiation necrosis but has some limitations; may also correlate with tumor grade or provide the optimal area for biopsy
 - ▶ Limitations: Accuracy of interpretations

¹ The imaging modalities listed may not be available at every institution.

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF BRAIN TUMOR SURGERY

Guiding Principles

- Gross total resection when appropriate
- Minimal surgical morbidity
- Accurate diagnosis

Factors

- Age
- PS
- Feasibility of decreasing the mass effect with surgery
- Resectability, including number of lesions, location of lesions, and time since last surgery (recurrent patients)
- New versus recurrent tumor
- Suspected pathology – benign vs. malignant, possibility of other non-cancer diagnoses, projected natural history
- For patients with *IDH1* mutations, there is evidence to suggest that a supramarginal resection is most appropriate, which would include not only enhancing areas but also T2/flair areas when appropriate in terms of a safe surgical approach, with the use of any and all surgical adjuncts possible.¹

Options

- Gross total resection where feasible
- Stereotactic biopsy²
- MRI-guided laser interstitial thermal therapy (LITT)³⁻⁸ (category 2B)
 - ▶ LITT may be considered for patients who are poor surgical candidates (craniotomy or resection). Potential indications include relapsed brain metastases, radiation necrosis, glioblastomas, and other gliomas.^{9,10}
- Open biopsy/debulking followed by planned observation or adjuvant therapy
- Systemic therapy implants, when indicated (see footnote x on [GLIO-8](#))
- Carmustine polymer wafer may be placed in the tumor resection cavity of patients.^{1,11}

Tissue

- Sufficient tissue to pathologist for neuropathology evaluation and molecular correlates
- Frozen section analysis when possible to help with intraoperative decision-making
- Review by experienced neuropathologist
- Postoperative brain MRI should be performed within 48 hours for gliomas and other brain tumors to determine the extent of resection. Postoperative spine MRI should be delayed by at least 2–3 weeks to avoid post-surgical artifacts.
- The extent of resection should be judged on the postoperative study and used as a baseline to assess further therapeutic efficacy or tumor progression.

Surgical Adjuncts

- A number of surgical adjuncts can be considered to facilitate safe brain tumor surgery, including use of an intraoperative microscope, frameless stereotactic image guidance, preoperative functional MRI and/or diffusion tensor imaging (DTI) fiber tracking, awake craniotomy, motor and/or speech mapping, intraoperative MRI, and intraoperative fluorescence-guided surgery with 5-ALA.

PRINCIPLES OF RADIATION THERAPY FOR BRAIN AND SPINAL CORD

Adult Low-Grade Diffuse Glioma: WHO Grade 2 Oligodendroglioma (*IDH*-mutant, 1p19q codeleted), WHO Grade 2 *IDH*-Mutant Astrocytoma

- Tumor volumes are best defined using pre- and postoperative MRI, usually T2 fluid-attenuated inversion recovery (FLAIR) and T1 post-contrast sequences, to define gross tumor volume (GTV). Clinical target volume (CTV) is created by expanding GTV by 1–2 cm margin editing off anatomic boundaries. The planning target volume (PTV) should receive 50–54 Gy in 1.8–2.0 Gy fractions, and doses as low as 45 Gy may also be appropriate.¹⁻³ Daily image guidance is required if smaller PTV margins are used (≤ 3 mm).
- New MRI for radiation treatment planning is recommended as there can be changes in mass effect, tumor bed, and cytotoxic edema. Distinguishing non-enhancing tumor from vasogenic edema on T2 FLAIR can be challenging and may warrant consultation with a neuroradiologist to inform treatment planning.
- For low-grade circumscribed gliomas (eg, PA), a smaller CTV margin (1 cm) is appropriate.

High-Grade Diffuse Glioma: Glioblastoma, WHO Grade 3 Oligodendroglioma (*IDH*-mutant, 1p19q codeleted), WHO Grade 3 or 4 *IDH*-Mutant Astrocytoma *Simulation and Treatment Planning*

- Tumor volumes are best defined using pre- and postoperative MRI imaging using post-contrast T1 and FLAIR/T2 sequences to define GTV. To account for sub-diagnostic tumor infiltration, the GTV is expanded 1–2 cm (CTV) for grade 3 and 4 tumors. Although trials in glioblastoma have historically used CTV expansion in the range of 2 cm, smaller CTV expansions are supported in the literature and can be appropriate. A PTV margin of 3–5 mm is typically added to the CTV to account for daily setup errors and image registration. Daily image guidance is required if smaller PTV margins are used (≤ 3 mm). When edema as assessed by T2/FLAIR is included in the initial phase of treatment, fields are usually reduced for the last phase of treatment (boost). The boost target volume will typically encompass only the gross residual tumor and the resection cavity. A range of acceptable CTV margins exists. Both strategies appear to produce similar outcomes.⁴
- Consider proton therapy for patients with good long-term prognosis (grade 2 gliomas, grade 3 *IDH*-mutant tumors,⁵ and 1p19q codeleted tumors⁶) to better spare uninvolved brain and preserve cognitive function.

RT Dosing Information

- The recommended dose is 60 Gy in 2.0 Gy fractions or 59.4 Gy in 1.8 Gy fractions.
- A slightly lower dose, such as 54–55.8 Gy in 1.8 Gy or 57 Gy in 1.9 Gy fractions, can be applied when the tumor volume is very large, there is brainstem/spinal cord involvement, or for grade 3 astrocytoma.
- If a boost volume is used, the initial phase of the RT plan will receive 46 Gy in 2 Gy fractions or 45–50.4 Gy in 1.8 Gy fractions. The boost plan will typically then receive 14 Gy in 2 Gy fractions or 9–14.4 Gy in 1.8 Gy fractions.⁴
- In poorly performing patients or older patients, a hypofractionated accelerated course should be considered with the goal of completing the treatment in 2–4 weeks. Typical fractionation schedules are 34 Gy/10 fractions or 40.05 Gy/15 fractions.^{7,8} Alternatively, a shorter fractionation schedule of 25 Gy/5 fractions may be considered for older and/or frail patients with smaller tumors for whom a longer course of treatment would not be tolerable.⁹

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF RADIATION THERAPY FOR BRAIN AND SPINAL CORD

Reirradiation for Gliomas

- Reirradiation of tumors of the CNS can be done safely in select circumstances, but requires careful attention to treatment technique and taking into account such patient-specific factors such as size of intended target volume, prior and cumulative doses to critical structures, and interval from the preceding radiotherapy course. While improved tumor control can be seen in appropriately selected patients, the impact on quality of life (QOL) and overall survival can vary by histology and patient PS.
- Highly focal techniques like intensity-modulated RT (IMRT), proton therapy, or SRS may be required in these reirradiation settings in order to improve dose distribution to critical structures, and reduce overlap with prior radiation fields.
- Recurrence of glioma can be managed with reirradiation in select scenarios when clinical trial options and new systemic therapy options are limited. Target volumes will be defined using contrast-enhanced T1 and T2 FLAIR MRI images. Normal tissues should include the brain, brainstem, optic nerves, optic chiasm, and cochlea. Radiation dose should be optimized and conformed to the target volume, while diminishing dose to critical structures. Treatment may be performed with highly focused modern SRS techniques for lower volume disease¹⁰; fractionated IMRT, including doses of 35 Gy in 10 fractions for recurrent glioblastoma¹¹; and proton therapy to help spare previously irradiated normal brain. For recurrence of lower grade gliomas, more extended fractionation schedules may be considered, especially if there is a longer interval between the first and second course of radiotherapy. Image-guided radiotherapy (IGRT) using imaging techniques may be used during treatment to ensure accuracy.

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF RADIATION THERAPY FOR BRAIN AND SPINAL CORD

Adult Intracranial and Spinal Ependymoma

• Limited Fields:

▶ Intracranial tumor volumes are best defined using pre- and postoperative MRI imaging, usually enhanced T1 and/or FLAIR/T2. GTV is defined as anatomic areas that are touched by preoperative tumor volume plus postoperative signal abnormality as seen on MRI.

▶ RT Dosing Information:

◊ CTV (GTV plus 1–2 cm margin) should receive 54–59.4 Gy in 1.8–2.0 Gy fractions. PTV margin of 3–5 mm is typically added to the CTV to account for daily setup errors and image registration.

• Craniospinal:

▶ To reduce toxicity from CSI in adults, consider the use of IMRT or protons if available (for patients with positive CSF or known metastatic disease).

▶ RT Dosing Information:

◊ Whole brain and spine (to bottom of thecal sac) receive 36 Gy in 1.8 Gy fractions, followed by limited field to spine lesions to 45 Gy. (Gross metastatic lesions below the conus could receive higher doses of 54–60 Gy.)^{12,13}

◊ Primary intracranial site should receive total dose of 54–59.4 Gy in 1.8–2.0 Gy fractions.

◊ Consider boosting any gross intracranial metastatic sites to a higher dose while respecting normal tissue tolerances.

• Spine Ependymoma:

▶ For spine ependymomas, see section on primary spinal cord tumors ([BRAIN-C 4 of 9](#)).^{14,15}

▶ CTV margins of 1–2 cm in the superior and inferior directions are recommended.

▶ PTV margin of 3–5 mm is typically added to the CTV to account for daily setup errors and image registration.

Adult Medulloblastoma

• Standard Risk for Recurrence:

▶ Preferred regimen is 23.4 Gy CSI^{16,17,††} with involved field boost to the primary brain site to 54–55.8 Gy¹ in patients who will receive adjuvant chemotherapy. For patients who are unable to receive adjuvant chemotherapy, typically doses of 30–36 Gy CSI^{16,†} with involved field boost to the primary brain site to 54–55.8 Gy are used.

• High Risk for Recurrence:

▶ 36 Gy CSI^{17,†} with involved field boost to primary brain site to 54–55.8 Gy with adjuvant systemic therapy.

◊ Focal spine boost to areas of gross disease, or dose escalation of CSI to 39.6 Gy may be indicated for patients with gross disease on spine MRI.

†To reduce toxicity from CSI in adults, consider the use of IMRT or protons if available.

††Regimen supported by data from pediatric trials only.

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF RADIATION THERAPY FOR BRAIN AND SPINAL CORD

Primary CNS Lymphoma

- **WBRT is typically withheld in the primary setting in patients treated with systemic therapy.**
 - ▶ **RT Dosing:**
 - ◇ **When used, low-dose WBRT should be limited to 23.4 Gy in 1.8 Gy fractions following a CR to systemic therapy.¹⁸**
 - ◇ **For less than CR, consider WBRT to 23.4–36 Gy followed by a limited field boost to gross disease to a bioequivalent dose of 45 Gy. In select cases, focal radiation boost or focal radiation to residual disease only may be considered.¹⁹⁻²⁴**
 - ▶ **For patients who are not candidates for systemic therapy:**
 - ◇ **WBRT doses of 24–36 Gy followed by a boost to gross disease for a total dose of 45 Gy.**

Primary Spinal Cord Tumors

- ▶ **RT Dosing:**
 - ◇ **Doses of 45–54 Gy are recommended using fractions of 1.8 Gy.**
 - ◇ **In tumors below the conus medullaris higher doses up to 60 Gy may be delivered.**
 - ◇ **CTV margins of 1–2 cm in the superior and inferior directions are recommended.**
 - ◇ **PTV margins of 3–5 mm are typically added to the CTV to account for daily setup errors and image registration.**
 - ◇ **In some instances focal SRS/SBRT to spinal tumors like hemangioblastoma may be appropriate, with care to respect normal tissue constraints of spinal cord and surrounding structures.²⁵**
 - ◇ **Proton therapy may also be helpful in the setting of primary spinal cord tumors to better spare surrounding normal tissues, uninvolved cord, and nerve roots.**

Note: All recommendations are category 2A unless otherwise indicated.

**BRAIN-C
4 OF 9**

PRINCIPLES OF RADIATION THERAPY FOR BRAIN AND SPINAL CORD

Meningiomas

- **General Treatment Information**

- ▶ If appropriate, may be treated using SRS or fractionated SRS.
- ▶ Highly conformal fractionated RT techniques (eg, 3D conformal RT [3D-CRT], IMRT, volumetric modulated arc therapy [VMAT], proton therapy) are recommended to spare critical structures and uninvolved tissue.
- ▶ Stereotactic or image-guided therapy is recommended when using tight margins or when close to critical structures.

- **WHO Grade 1 Meningiomas:**

- ▶ **RT Dosing:**

- ◊ 54 Gy may be reduced to 50–50.4 Gy range near critical organs at risk.^{26,27}
- ◊ WHO grade 1 meningiomas may also be treated with SRS doses of 12–16 Gy in a single fraction when appropriate, or consider hypofractionated SRT (25–30 Gy in 5 fractions) if near critical structures. Optimal dosing has not been determined.

- **WHO Grade 2 Meningiomas:**

- ▶ **General Treatment Information**

- ◊ Treatment should be directed to gross tumor (if present), surgical bed, and a margin (0.5–2 cm) to account for microscopic disease.
- ◊ Limit margin expansion into the brain parenchyma if there is no evidence of brain invasion. CTVs should be edited and constrained anatomically to encompass path of extension into meningeal and dural surfaces.

- ▶ **RT Dosing:**

- ◊ 54–60 Gy in 1.8–2.0 Gy fractions. Higher doses (59.4–60 Gy) recommended for patients with subtotally resected disease or recurrent tumors.

- ▶ **Select WHO grade 2 cases:** Recurrence post prior radiation and smaller size amenable to SRS may also be treated with SRS doses of 16–20 Gy in a single fraction when appropriate, or consider hypofractionated SRT (27.5–30 Gy in 5 fractions) if near critical structures.^{28,29} Optimal dosing has not been determined.

- **WHO Grade 3 Meningiomas:**

- ▶ **General Treatment Information**

- ◊ Treat as malignant tumors with treatment directed to gross tumor (if present), surgical bed, and a margin (2–3 cm).

- ▶ **RT Dosing:**

- ◊ 59.4–60 Gy in 1.8–2.0 Gy fractions. Higher doses (66–70 Gy at 2 Gy per fraction) may be needed to provide durable local control of gross tumor but require highly conformal technique and respect of normal tissue tolerances. Using techniques like IMRT with simultaneous integrated boost (SIB) are helpful in these instances.

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF RADIATION THERAPY FOR BRAIN AND SPINAL CORD

Brain Metastases

- SRS is generally preferred over WBRT for limited brain metastases.
- SRS treatment planning MRI with thick 1-mm slice T1+c sequence is recommended and should be obtained within 14 days of initiation of SRS.³⁰
 - ▶ Maximum marginal doses from 15–24 Gy based on tumor volume is recommended.³¹⁻³⁴
 - ◇ Consider fractionated SRS for brain tumor >2 cm and/or for situations where a single-fraction SRS plan exceeds normal tissue constraints (eg, V12 brain [volume of normal brain plus target volumes receiving 12 Gy] of >10 cm).³⁵
 - Most common multi-fraction SRS doses include: 27 Gy in 3 fractions and 30 Gy in 5 fractions.
 - ◇ Consider preoperative SRS in select cases when logistically feasible to potentially decrease risk of post-treatment meningeal recurrence (category 2B).
 - ◇ Postoperative single multi-fraction SRS: Local recurrence rates after brain metastasis resections remain high (in the range of 50% at 1–2 years) even in the setting of a radiographic gross total resection. Postoperative SRS to the surgical cavity is supported by randomized data to improve local control over observation and to offer similar overall survival and superior cognitive preservation to postoperative WBRT.^{36,37} A consensus statement regarding radiation target delineation has been published.³⁸ Multi-fraction SRS may be preferred for larger cavities.³⁹ Common dose-fractionation schedules include 16–20 Gy in 1 fraction, 24–27 Gy in 3 fractions, and 30 Gy in 5 fractions.
- WBRT: Standard doses include 30 Gy in 10 fractions and 20 Gy in 5 fractions. WBRT can be done with or without HA + memantine. HA-WBRT (plus memantine) 30 Gy in 10 fractions is preferred for patients with a better prognosis (≥4 months) and no metastases within 5 mm of the hippocampi.⁴⁰
 - ▶ For patients with poor predicted prognosis and with symptomatic brain metastases, standard WBRT of 20 Gy in 5 fractions is a reasonable option.⁴¹ If WBRT is given, for patients with a better prognosis, consider memantine during and after WBRT for a total of 6 months.⁴²

Leptomeningeal Metastases

- ▶ Volume and dose depend on primary tumor histology and goals of care. For CSI in patients with metastatic solid tumor malignancies, techniques in maximizing bone marrow sparing should be considered (protons when available, or conformal photon-based techniques/IMRT).^{43,44}

Note: All recommendations are category 2A unless otherwise indicated.

BRAIN-C
6 OF 9

PRINCIPLES OF RADIATION THERAPY FOR BRAIN AND SPINAL CORD

Metastatic Spine Tumors

• General Treatment Information

- ▶ Doses to vertebral body metastases will depend on patient's PS, spine stability, location in relationship to spinal cord, primary histology, presence of epidural disease, and overall treatment intent (pain relief, long-term local control, or cure).
- ▶ Stereotactic radiation approaches (SRS/stereotactic body radiotherapy [SBRT]) for spinal cases may be preferred for patients with life expectancy ≥ 3 months where tumor ablation is a goal of treatment, in tumors considered radioresistant (eg, renal cell, melanoma, sarcoma, hepatocellular, some colorectal and NSCLC cases), and in select patients for optimal pain relief.⁴⁵
- ▶ Stereotactic radiation approaches may also be preferred in the setting of tumor recurrence after prior radiation as a strategy to limit radiation dose to the spinal cord or other critical structures. Careful adherence to consensus guidelines for radiosurgery planning and delivery is recommended.^{39,46-47}

• RT Dosing:

- ▶ Generally, conventional EBRT doses of 8 Gy/1 fractions, 20 Gy/5 fractions, or 30 Gy/10 fractions can be used. It is critical to consider tolerance at the spinal cord and/or nerve root. In selected cases, or recurrences after previous radiation, SBRT is appropriate.
- ▶ Common recommended doses for spine SRS/SBRT may include:
 - ◊ 16–24 Gy in 1 fraction;
 - ◊ 24–28 Gy in 2 fractions;
 - ◊ 24–30 Gy in 3 fractions;
 - ◊ 30–40 Gy in 5 fractions
- ▶ In patients with uncomplicated spine metastases that are treated primarily for pain relief, 8 Gy in 1 fraction has been shown to provide equivalent pain control to longer fractionation schedules. Single-fraction treatment is more convenient for patients and an important consideration for patients with poor prognoses. This treatment may be associated with higher rates of retreatment, and is a consideration for patients with a prognosis that exceeds 6 months.
- ▶ When lower biologically effective dose (BED) regimens are utilized upfront (ie, BED ≤ 60 Gy, which includes up to 20 Gy in 5 fractions but does not include 30 Gy in 10 fractions), retreatment with similar BED regimens, such as 20 Gy in 5 fractions or 8 Gy in 1 fraction, can safely be considered as early as 6 weeks from initial treatment for pain relief.
- ▶ In other cases of retreatment, doses ranging from 15 Gy in 1 fraction with SBRT to 40 Gy in 20 fractions with a conformal approach have been utilized for tumor control, with careful consideration of tolerance of the spinal cord and/or nerve roots. In these instances, it is generally recommended that 6 months or more of time between treatments is required.^{36,41}

PRINCIPLES OF BRAIN AND SPINE TUMOR MANAGEMENT

General

Patients diagnosed with a tumor involving the brain, spinal cord, and related support structures should be referred to practitioners who are experienced in the diagnosis and management of these lesions.^a The patient may (and should) be presented with options for care, which may include procedures or treatments best done by other specialists. The care options should then be discussed with the patient and their chosen supports in a manner that is understandable and culturally and educationally sensitive. It is strongly encouraged to discuss goals of care with the patient.

Multidisciplinary Care

During the course of their treatment, most patients will be seen by multiple subspecialists. Close and regular communication among all providers across disciplines is essential. Brain tumor board or multidisciplinary clinic care models are strongly recommended. These models facilitate interactions among multiple subspecialists, ideally including allied health services (ie, physical, occupational, and speech therapies; nursing; psychology; social work) for optimizing treatment plan recommendations.

- Patients with malignant primary brain tumors can benefit from inpatient rehabilitation as deemed appropriate.
- As treatment proceeds, it is important that the patient and family understand the role of each team member. One practitioner should be identified early on as the main point of contact for follow-up care questions. This individual can facilitate referral to the appropriate specialist.
- Offering patients the option of participation in a clinical trial is strongly encouraged. Practitioners should discuss any local, regional, and national options for which the patient may be eligible and the advantages and disadvantages of participation. Centers treating neuro-oncology patients are encouraged to participate in large collaborative trials in order to have local options to offer patients.
- Patients should be educated on the importance of informed consent and side effects when receiving systemic therapy.
- Throughout treatment the patient's QOL should remain the highest priority and guide clinical decision-making. While responses on imaging are benchmarks of successful therapy, other indicators of success such as overall well-being, function in day-to-day activities, social and family interactions, nutrition, pain control, long-term consequences of treatment, and psychological issues must be considered.
- Patients should be informed of the possibility of pseudoprogression, its approximate incidence, and potential investigations that may be needed in the event that pseudoprogression is suspected. Close follow-up imaging, MR perfusion, MR spectroscopy, PET/CT imaging, and repeat surgery may be necessary if clinically indicated. Educate patients on the uncertainty of imaging as a whole, and the potential need for corollary testing to interpret scans.
- For patients with spine tumors, it is important to assemble a multidisciplinary team to integrate diagnosis, treatment, symptom management, and rehabilitation. Patients with spine tumors have complex physical, psychological, and social care needs.

[References \(BRAIN-D 6 of 7\)](#)

^a Depending on local referral patterns and available expertise, this physician may be a neurosurgeon, neurologist, medical oncologist, or radiation oncologist.

Note: All recommendations are category 2A unless otherwise indicated.

Continued

**BRAIN-D
1 OF 7**

PRINCIPLES OF BRAIN AND SPINE TUMOR MANAGEMENT

Multidisciplinary Care (continued)

Optimal management requires a multidisciplinary team including those with the following expertise: neuro-oncology/medical and radiation oncology; surgery (ie, neurosurgery, orthopedic surgery, surgical oncology); radiology; interventional pain specialties; physical and rehabilitation medicine; psychiatry; bowel and bladder care, back care, and ambulation support; physical therapy; occupational therapy; psychological and/or social services; and nutritional support.

- Practitioners should become familiar with palliative and hospice care resources that are available in their community in order to help educate patients and families that involvement of these services does not indicate a state of hopelessness, no further treatment, or abandonment. Palliative and pain management care should be integrated into management of neuro-oncology patients early in the course of their treatment¹ ([NCCN Guidelines for Palliative Care](#)).

Medical Management

Corticosteroids

- Steroid therapy should be carefully monitored. If a patient is asymptomatic, steroids may be unnecessary. In general, the lowest dose of steroids should be used for the shortest time possible.^b Downward titration of the dose should be attempted whenever possible. Twice-daily (BID) or once-daily dosing is recommended for dexamethasone. Patients with extensive mass effect should receive steroids for at least 24 hours before RT. Patients with a high risk of gastrointestinal (GI) side effects (ie, perioperative patients, prior history of ulcers/GI bleed, receiving nonsteroidal anti-inflammatory drugs [NSAIDs] or anticoagulation) should receive H2 blockers or proton pump inhibitors. Care should be taken to watch for development of steroid side effects.^c
- Consider prophylactic treatment of pneumocystis jiroveci pneumonia (PJP) for patients undergoing long-term steroid therapy ([NCCN Guidelines for Prevention and Treatment of Cancer-Related Infections](#)).

Mass Effect, Brain Edema, Radiation Necrosis

- Careful questioning for subtle symptoms should be undertaken if edema is extensive on imaging.
- Symptomatic:
 - ▶ Corticosteroids or confirmatory diagnostic study^{2,3}
 - ◇ Consider surgical resection
 - ◇ Consider bevacizumab, re-evaluate every 4–6 weeks^{4,5}
 - ◇ Slow steroid taper, follow serial MR every 2–3 months
- If asymptomatic:
 - ▶ Follow serial MR every 2–3 months
- LITT is a minimally invasive technique using photothermal technology and can be considered on a case-by-case basis for treatment of radiation necrosis in patients with a history of RT for primary brain tumor or metastatic disease.^{6,7} Consultation with neurosurgeons trained in LITT should be done when the procedure is considered.

^b An exception to this rule is in the case of suspected CNS lymphoma. Steroids should be avoided where possible ([PCNS-1](#)) prior to biopsy to allow for the best chance of diagnosis.

^c Refractory hyperglycemia, skin changes, visual changes, fluid retention, and myopathy. If any of these changes occur, it is imperative to evaluate potential palliative treatments for them and also to evaluate the current dose of steroids to see if it can be reduced in an attempt to mitigate these side effects. Clinical monitoring for adrenal insufficiency is recommended when weaning steroids for patients who have been on long-term steroid therapy.

Note: All recommendations are category 2A unless otherwise indicated.

BRAIN-D
2 OF 7

PRINCIPLES OF BRAIN AND SPINE TUMOR MANAGEMENT

Seizures

- Seizures are frequent in patients with primary or metastatic brain tumors. Despite this, studies have shown that the use of older, “traditional” anti-seizure medications, including phenytoin, phenobarbital, and valproic acid as prophylaxis against seizures in patients who have never had a seizure or who are undergoing neurosurgical procedures, is ineffective and is not recommended. Newer agents (ie, levetiracetam, topiramate, lamotrigine, pregabalin) have not yet been systematically studied.
- Seizure prophylaxis is not recommended as routine in asymptomatic patients but is reasonable to consider perioperatively.
- Many anti-seizure medications have significant effects on the cytochrome P450 system, and may have effects on the metabolism of numerous chemotherapeutic agents such as irinotecan, gefitinib, erlotinib, and temsirolimus among others. When possible, such enzyme-inducing antiepileptic drugs (EIAEDs) should be avoided (ie, phenytoin, phenobarbital, carbamazepine), and non-EIAEDs should be used instead (ie, levetiracetam, topiramate, valproic acid, lacosamide). Patients should be closely monitored for any adverse effects of the anti-seizure medications or chemotherapeutic agents.
- Consult with neurologists for the management of seizures.
- Refer to the Epilepsy Foundation (www.epilepsy.com).

BRAIN-D
3 OF 7

PRINCIPLES OF BRAIN AND SPINE TUMOR MANAGEMENT

Medical Management (continued)

Endocrine Disorders

- Endocrinopathies are common in patients with brain tumors. This may be affected by concomitant steroid use as well as by radiotherapy, surgery, and certain medical therapies. Patients who present with a declining sense of well-being or QOL should be evaluated not only for abnormalities related to their hypothalamic pituitary and adrenal axis, but also with regard to thyroid and gonad function. For patients who received prior RT, long-term monitoring of the hypothalamic pituitary and adrenal axis may be considered (eg, adrenocorticotrophic hormone [ACTH] stimulation test, thyroid monitoring).

Fatigue (See the [NCCN Guidelines for Cancer-Related Fatigue](#))

- Fatigue is commonly experienced by patients with brain tumors. This symptom can be severe, persistent, emotionally overwhelming, and not related to the degree or duration of physical activity. Screening should be initiated to identify any underlying medical sources of this symptom, after which patients should be encouraged to start a physical exercise program or increase their level of activity if already exercising, as physical exercise has the best evidence for the prevention and treatment of cancer-related fatigue (See Healthy Lifestyles in [NCCN Guidelines for Survivorship](#)). More data are needed on the use of CNS stimulants.
- The effects of psychostimulants on cancer-related fatigue has not been proven, but psychostimulants did improve attention in patients with cancer, thus improving cognitive engagement to allow exercise.

Psychiatric Disease (See the [NCCN Guidelines for Distress Management including NCCN Distress Thermometer \[DIS-A\]](#))

- There is increasing evidence that physical exercise can help reduce anxiety and improve mood. Patients should be encouraged to start an exercise routine at diagnosis (See Healthy Lifestyles in [NCCN Guidelines for Survivorship](#)).
- Depression and/or anxiety is common in neuro-oncology patients. These symptoms are greater than simple sadness or anxiety associated with the diagnosis of a tumor. The vegetative symptoms associated with depression or severe anxiety may become very disabling for the patient and distressing for the family. These symptoms will respond to psychotropic medications as they do in patients with no tumors. If less severe, strong support from behavioral health allies and other qualified counselors is also extremely beneficial. All oncology providers and team members should be sensitive to these symptoms and inquire about them in follow-up visits in order to determine if the patient may be a candidate for psychological or psychiatric treatment. Communication between members of the patient's health care team regarding the patient's response to treatment is important.⁸ Anti-seizure medications, anxiolytics, some systemic therapy agents, antiemetics, and other agents used directly in cancer therapy may affect mental status, alertness, and mood. Alterations in thought processes should trigger an investigation for any treatable causes, including endocrine disorders, infection, side effects of medication, or tumor progression.

Venous Thromboembolism (VTE) (See the [NCCN Guidelines for Cancer-Associated Venous Thromboembolic Disease](#))

Hearing Loss

- Bevacizumab is recommended for Neurofibromatosis type 2 vestibular schwannomas with hearing loss.⁹

PRINCIPLES OF BRAIN AND SPINE TUMOR MANAGEMENT

Assessment and Management of Neurocognitive Dysfunction

- Up to 90% of individuals with supratentorial brain tumors experience some degree of neurocognitive dysfunction.¹⁰⁻¹²
- Degree of neurocognitive dysfunction can vary as a result of a variety of factors not limited to tumor- and treatment-related effects. For instance, CNS tumor size, grade, and location influence the likelihood, degree of severity, and specific pattern of cognitive symptoms.¹⁵⁻¹⁵ In glioma, *IDH1* mutation confers a more favorable cognitive prognosis at the time of initial diagnosis and after surgery.¹⁶⁻¹⁸ Treatments for brain tumors can also negatively impact cognition.⁹⁻²¹
- Neurocognitive impairment has been shown to be a sensitive indicator of tumor progression^{22,23} and a predictor of overall survival in glioma.^{24,25} Perhaps more importantly, neurocognitive deficits result in impaired ability to work²⁶ and instrumental activities of daily living²⁷ or functional independence, directly hindering QOL.²⁸
- Neurocognitive screening tools, such as the Mini-Mental State Examination and Montreal Cognitive Assessment (MMSE;²⁹ MoCA³⁰), are insensitive to important neurocognitive changes such as executive function, sustained attention, and processing speed.³¹⁻³³ Neuropsychological evaluation is the gold standard for assessment of neurocognitive function, as it objectively and comprehensively characterizes cognitive, behavioral, and emotional issues related to the patient's disease as well as cognitive strengths and identifies treatable risk factors that contribute to neurocognitive difficulty and reduced functioning (eg, depression,³⁴ sleep disturbance).³⁵ Evaluations provide patient-specific recommendations,³⁶ which may include implementation of compensatory strategies in daily activities, referral for psychotherapy or neurocognitive rehabilitation, and guidance regarding work or school accommodations. There is increasing evidence that physical exercise can help preserve cognitive function. Patients should be encouraged to start an exercise routine at diagnosis (See Healthy Lifestyles in [NCCN Guidelines for Survivorship](#)).
- Where available, neuropsychological evaluation should be performed as needed based on physician assessment to monitor for neurocognitive decline and/or recovery, as well as determine patient-centered treatment recommendations aimed at maximizing safety, functioning, and QOL.³⁷

Health Maintenance (See the [NCCN Guidelines for Survivorship](#))

PRINCIPLES OF BRAIN TUMOR PATHOLOGY

- Incorporation of relevant diagnostic markers, including histopathologic and molecular information, as per the 5th edition of the WHO 2021 Classification of Tumors of the Central Nervous System, should be considered standard practice for tumor classification.
- Molecular/genetic characterization complements standard histologic analysis, providing additional diagnostic and prognostic information that can greatly improve diagnostic accuracy, influence treatment selection, and improve management decision-making.

Standard Histopathologic Examination and Classification

- Histologic subgrouping of CNS neoplasms provides valuable prognostic information, as is described in the WHO 2021 Classification of Tumors of the Central Nervous System.¹
- Interobserver discrepancies in histologic diagnosis and grading are a recognized issue, due to the inherently subjective nature of certain aspects of histopathologic interpretation (eg, astrocytic vs. oligodendroglial morphology). Also, surgical sampling does not always capture all the relevant diagnostic features in morphologically heterogeneous tumors.
- Even so, the traditional histologic classification of CNS neoplasms into primary neuroectodermal neoplasms (eg, glial, neuronal, embryonal), other primary CNS neoplasms (eg, lymphoma, germ cell, meningeal), metastatic neoplasms, and non-neoplastic conditions mimicking tumors remains fundamental to any pathologic assessment.

Molecular Characterization

- With the use of genetic and molecular testing, histologically similar CNS neoplasms can be differentiated more accurately in terms of prognosis and, in some instances, response to different therapies.²⁻⁶
- Molecular characterization of primary CNS tumors has substantially impacted clinical trial eligibility and risk stratification in the past 10 years, thereby evolving the standard of care towards an integrated tumor diagnosis in neuro-oncology.
- Molecular/genetic characterization does not replace standard histologic assessment, but serves as a complementary approach to provide additional diagnostic and prognostic information that often enhances treatment selection.
- Genome-wide profiling of CpG methylation patterns has been shown to be a powerful way to classify brain tumors, including those with equivocal histologic features.⁷ While this testing method is rapidly gaining popularity, it cannot yet be regarded as a gold standard for diagnosis in all cases, because some tumors have methylation patterns that are so rare they have not yet been correlated with specific clinical/biological behavior.
- Some diffusely infiltrative astrocytomas lack the histologic features of glioblastoma (necrosis and/or microvascular proliferation) but have the molecular hallmarks of glioblastoma, including one or more of the following: *IDH* wild-type; *EGFR* amplification; gain of chromosome 7 and loss of chromosome 10; and *TERT* promoter mutation. In such cases, the tumor can now be diagnosed as "Glioblastoma, *IDH*-wild-type, WHO grade 4." Because these tumors have similar clinical outcomes as typical grade 4 glioblastomas, they may be treated as such.^{8,9}

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF BRAIN TUMOR PATHOLOGY: MOLECULAR MARKERS

The following molecular markers are often used by neuropathologists to facilitate characterization of gliomas and/or by neuro-oncologists to guide treatment decisions:

Molecular Characterization (continued)

- The Panel encourages molecular testing of glioblastoma because if a driver mutation (such as *BRAF* V600E mutation or *NTRK* fusion) is detected, it may be reasonable to treat with a targeted therapy on a compassionate use basis and/or the patient may have more treatment options in the context of a clinical trial. Molecular testing also has a valuable role in improving diagnostic accuracy and prognostic stratification that may inform treatment selection.
- The following comprises a high-yield list of alterations as informed by the 2021 WHO classification system, and is not comprehensive for all clinically relevant molecular alterations in all gliomas.
 - ▶ Mutations: *IDH1* R132 and *IDH2* R172, *TERT* promoter, *ATRX*, *EGFR*, *BRAF* V600E, and *H3-3A* mutation (K27 or G34)
 - ▶ Copy number alterations: 1p/19q codeletion, *EGFR* amplification, gain of chromosome 7, loss of chromosome 10, and *CDKN2A/B* deletion.
- Next-generation sequencing (NGS) is now the preferred approach for pathologic workup of CNS tumors, as it screens for multiple diagnostic and prognostic mutations in one test.
- NGS results from tumor tissue cannot prove the existence of a heritable cancer predisposition syndrome (eg, Lynch syndrome, Li-Fraumeni syndrome). If such a syndrome is suspected based on clinical and family history, genetic counseling and testing of "germline" DNA from the bloodstream is required.

IDH1 and *IDH2* Mutation

- Recommendation: *IDH* mutation testing is required for the workup of all gliomas.
- Description: *IDH1* and *IDH2* are metabolic enzymes. Specific mutations in genes encoding these enzymes lead to the aberrant production of D-2-hydroxyglutarate, an oncometabolite that causes epigenetic modifications in affected cells.⁹ Diffusely infiltrative astrocytomas with *IDH* mutation are mostly WHO grade 2–3. However, some develop the traditional grade 4 histologic features of necrosis and/or microvascular proliferation, which does suggest more aggressive behavior and worse prognosis, but are still not as severe as *IDH* wild-type glioblastomas. Such tumors are now

called "Astrocytoma, *IDH*-mutant, WHO grade 4," to distinguish them from *IDH* wild-type glioblastoma.^{9,10} Some *IDH*-mutant astrocytomas do not show grade 4 histologic features, yet contain homozygous deletion in *CDKN2A/B*. These should also be called "Astrocytoma, *IDH*-mutant, WHO grade 4."¹⁰⁻¹⁵

- Detection: The most common *IDH1* mutation (R132H) is reliably screened by mutation-specific immunohistochemistry (IHC), which is recommended for all patients with glioma. If the R132H immunostain result is negative, in the appropriate clinical context, sequencing of *IDH1* and *IDH2* is highly recommended to detect less common *IDH1* and *IDH2* mutations. Prior to age 55 years, sequencing of *IDH1* and *IDH2* is required if the R132H immunostain result is negative, or if the glioma is only grade 2 or 3 histologically. Standard sequencing methods include Sanger sequencing, pyrosequencing, and NGS, and can be performed on formalin-fixed, paraffin-embedded tissue.⁸
- Diagnostic value:
 - ▶ *IDH* mutations define WHO grade 2 and 3 astrocytomas and oligodendrogliomas, and grade 4 *IDH*-mutant astrocytomas. Their presence distinguishes lower-grade gliomas from glioblastomas, which are *IDH* wild-type.^{10,16} Detection of these mutations in a specimen that is otherwise equivocal for tumor may also be regarded as evidence that a diffusely infiltrative glioma is present.⁸
 - ▶ True grade 1 non-infiltrative gliomas, such as PAs and gangliogliomas, do not contain *IDH* mutations. In such cases, detection of an *IDH* mutation indicates that the tumor is at least a grade 2 diffusely infiltrative glioma.⁸
- Prognostic value:
 - ▶ *IDH* mutations are commonly associated with *MGMT* (O6-methylguanine-DNA methyltransferase) promoter methylation.⁴
 - ▶ *IDH1* or 2 mutations are associated with a relatively favorable prognosis and are important in stratification for clinical trials.¹⁷
 - ▶ In grade 2 or 3 infiltrative gliomas, wild-type *IDH1* or 2 is associated with increased risk of aggressive disease.⁴
 - ▶ *IDH1* or 2 mutations are associated with a survival benefit for patients treated with radiation or alkylating systemic therapy.^{18,19}

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF BRAIN TUMOR PATHOLOGY: MOLECULAR MARKERS

The following molecular markers are often used by neuropathologists to facilitate characterization of gliomas and/or by neuro-oncologists to guide treatment decisions:

Codeletion of 1p and 19q

- Recommendation: 1p/19q testing is an essential part of molecular diagnostics for oligodendroglioma.
- Description: This codeletion represents an unbalanced translocation (1;19)(q10;p10), leading to whole-arm deletion of 1p and 19q.²⁰
- Detection: The codeletion of 1p and 19q is detectable by array-based genomic copy number testing (preferable), or fluorescence in situ hybridization (FISH).
- Diagnostic value: 1p/19q codeletion is strongly associated with oligodendroglial histology and helps confirm the oligodendroglial character of tumors with equivocal or mixed histologic features.²¹
 - ▶ *IDH*-mutated gliomas that do NOT show loss of *ATRX* (for example, by IHC) should be strongly considered for 1p/19q testing, even if not clearly oligodendroglial by histology. Conversely, *IDH1* wild-type gliomas do not contain true whole-arm 1p/19q codeletion.²² Therefore, 1p/19q testing is unnecessary if a glioma is definitely *IDH* wild-type, and a glioma should not be regarded as 1p/19q-codeleted without an accompanying *IDH* mutation, regardless of test results.
 - ▶ A tumor should only be diagnosed as an oligodendroglioma if it contains both an *IDH* mutation and 1p/19q codeletion. Furthermore, the term “oligoastrocytoma” should no longer be used, as such morphologically ambiguous tumors can reliably be resolved into astrocytomas and oligodendrogliomas with molecular testing.²³
- Prognostic value: The codeletion confers a favorable prognosis and is predictive of response to alkylating systemic therapy with or without RT.^{24,25}

MGMT Promoter Methylation

- Recommendation: *MGMT* promoter methylation is an essential part of molecular diagnostics for all high-grade gliomas (grade 3 and 4).
- Description: *MGMT* is a DNA repair enzyme that reverses the DNA damage caused by alkylating agents, resulting in tumor resistance to TMZ and nitrosourea-based systemic therapy. Methylation of the *MGMT* promoter silences *MGMT*, making the tumor more sensitive to treatment with alkylating agents.²⁶
- Detection: There are multiple ways to test for *MGMT* promoter methylation, including methylation-specific polymerase chain reaction (PCR),²⁷ methylation-specific high-resolution melting, pyrosequencing,²⁸ and droplet-digital PCR. One study suggested that pyrosequencing is the best prognostic stratifier among glioblastomas treated with TMZ.^{29,30} However, quantitative methylation-specific (qMS)-PCR remains the assay that has had the most validation in clinical trials.²⁷
- Prognostic value:
 - ▶ *MGMT* promoter methylation is strongly associated with *IDH* mutations and genome-wide epigenetic changes (G-CIMP phenotype).⁴
 - ▶ *MGMT* promoter methylation confers a survival advantage in glioblastoma and is used for risk stratification in clinical trials.³¹
 - ▶ *MGMT* promoter methylation is particularly useful in treatment decisions for older adult patients with high-grade gliomas (grades 3–4).^{32,33}
 - ▶ Patients with glioblastoma that is not *MGMT* promoter methylated derive less benefit from treatment with TMZ compared to those whose tumors are methylated.³¹

Note: All recommendations are category 2A unless otherwise indicated.

BRAIN-E
3 OF 9

PRINCIPLES OF BRAIN TUMOR PATHOLOGY: MOLECULAR MARKERS

The following molecular markers are often used by neuropathologists to facilitate characterization of gliomas and/or by neuro-oncologists to guide treatment decisions:

ATRX Mutation

- Recommendation: *ATRX* mutation testing is required for the workup of glioma.
- Description:
 - ▶ *ATRX* encodes a chromatin regulator protein. Loss-of-function mutations enable alternative lengthening of telomeres.³⁴
- Detection: *ATRX* mutations can be detected by IHC for wild-type *ATRX* (loss of wild-type expression) and/or sequencing.³⁵
- Diagnostic value: *ATRX* mutations in glioma are strongly associated with *IDH* mutations, and are nearly always mutually exclusive with 1p/19q codeletion.³⁵ *ATRX* deficiency, coupled with *IDH* mutation and *TP53* mutation, is typical of astrocytoma. A lack of *ATRX* immunostaining in glioblastoma should trigger *IDH1/2* sequencing if *IDH1* R132H immunostaining is negative, due to the frequent co-occurrence of *ATRX* and *IDH* mutations.^{5,35}

TERT (Promoter Mutation)

- Recommendation: *TERT* promoter mutation testing is recommended for the workup of gliomas.
- Description: *TERT* encodes telomerase, the enzyme responsible for maintaining telomere length in dividing cells. *TERT* mutations found in gliomas are located in its noncoding promoter region, and cause increased expression of the *TERT* protein.³⁶
- Detection: *TERT* mutation can be detected by sequencing of the promoter region.³⁷
- Diagnostic value: *TERT* promoter mutations are nearly always present in 1p/19q codeleted oligodendroglioma, and are found in most glioblastomas. *TERT* promoter mutation, in combination with *IDH* mutation and 1p/19q codeletion, is characteristic of oligodendroglioma. Absence of *TERT* promoter mutation, coupled with the presence of mutant *IDH*, strongly suggests astrocytoma.
- Prognostic value: In the absence of an *IDH* mutation, *TERT* promoter mutation in diffusely infiltrative gliomas is associated with reduced overall survival compared to similar gliomas lacking *TERT* promoter mutation.^{4,38,39}
Combined *TERT* promoter mutation and *IDH* mutations in the absence of 1p/19q codeletion is an uncommon event, but such tumors have a prognosis as favorable as gliomas with all three molecular alterations.^{4,38}

H3-3A Mutation

- Recommendation: *H3-3A* and *HIST1H3B* mutation testing is recommended in the appropriate clinical context.
- Description:
 - ▶ The most common histone mutation in brain tumors, H3K27M, is caused by a lysine-to-methionine substitution in the *H3-3A* gene and inhibits the trimethylation of *H3.3* histone. G34 mutations are more common in cortical gliomas in children.⁴⁰⁻⁴²
 - ▶ Another variant in *H3-3A*, resulting in a G34V (or R) mutation in histone 3.3, is characteristic of some diffusely infiltrative gliomas arising not in the midline, but in the cerebral hemispheres. These gliomas tend to occur in children and younger adults and are *IDH* wild-type but *ATRX* and *TP53* mutant. Thus, the 5th edition of the WHO classification calls these tumors “Diffuse hemispheric glioma, *H3.3* G34-mutant, WHO grade 4.”¹
- Detection:
 - ▶ Diffuse midline gliomas should be screened for *H3-3A* mutations, specifically the H3K27M mutation. While sequencing is the gold standard, H3K27M-specific IHC, paired with H3K27 trimethylation immunostaining, is a reasonable alternative, especially when tissue is scarce. In these gliomas, H3K27M immunopositivity should be associated with loss of histone trimethylation immunostaining.⁴³⁻⁴⁷

Note: All recommendations are category 2A unless otherwise indicated.

BRAIN-E
4 OF 9

PRINCIPLES OF BRAIN TUMOR PATHOLOGY: MOLECULAR MARKERS

The following molecular markers are often used by neuropathologists to facilitate characterization of gliomas and/or by neuro-oncologists to guide treatment decisions:

- **Detection: continued**
 - ▶ Although a *K27M* histone antibody is available,⁴⁸ it is not 100% specific and interpretation can be difficult for non-experts. Therefore, screening by *H3-3A* and *HIST1H3B* sequencing is a viable alternative and the preferred approach, especially since it will also detect mutations in *G34*.
- **Diagnostic value:** Histone mutations most commonly occur in pediatric midline gliomas (eg, diffuse intrinsic pontine gliomas [DIPG]), although midline gliomas in adults can also contain histone mutations.⁵⁵ Their presence can be considered solid evidence of an infiltrative glioma, which is often helpful in small biopsies of midline lesions that may not be fully diagnostic with light microscopy or do not fully resemble infiltrative gliomas.^{40,41,49}
- **Prognostic value:** *K27M* gliomas typically do not have *MGMT* promoter methylation, and the mutation is an adverse prognostic marker in children and adults. The *G34* mutation does not appear to have any prognostic significance once the diagnosis of glioblastoma has been established.^{41,49,50}

BRAF Mutation

- **Recommendation:** *BRAF* fusion and/or mutation testing is recommended in the appropriate clinical context.
- **Description:** Activating mutations in *BRAF*, most commonly the V600E variant seen in other cancers (eg, melanoma), are present in a wide range of CNS tumors, including 60%–80% of supratentorial grade 2–3 PXAs, 30% of DNETs, 20% of grade 1 gangliogliomas, and 5% of grade 1 PAs. Diffusely infiltrative gliomas can also harbor a *BRAF* mutation, especially in children. *BRAF* V600E has even been found in nonneoplastic cortical dysplasia. In contrast, activating *BRAF* fusions can be seen in newer WHO entities

including diffuse leptomeningeal glioneuronal tumor and HGAP and occur predominately in PA of the posterior fossa, although some supratentorial PA also have this fusion.⁵¹⁻⁵³

- **Detection:** *BRAF* V600E is best detected by sequencing, and *BRAF* fusions can be detected with RNA sequencing or other PCR-based breakpoint methods that capture the main 16–9, 15–9, and 16–11 breakpoints between *BRAF* and its main fusion partner, *KIAA1549*. FISH is too unreliable to detect *BRAF* fusions.⁵¹
- **Diagnostic value:** The presence of a *BRAF* fusion is reliable evidence that the tumor is a PA, provided the histology is compatible. *BRAF* V600E is more complicated, as it can occur in a variety of tumors over all four WHO grades and requires integration with histology.⁵¹
- **Prognostic value:** Tumors with *BRAF* fusions tend to be indolent, with occasional recurrence but only rare progression to lethality. *BRAF* V600E tumors show a much greater range of outcomes and need to be considered in context with other mutations and clinicopathologic findings (eg, *CDKN2A/B* deletion). *BRAF* V600E tumors may respond to *BRAF* inhibitors such as vemurafenib, but comprehensive clinical trials are still ongoing.⁵⁴⁻⁵⁶

Ependymomas

- **Detection:**
 - ▶ Posterior fossa ependymomas are categorized as two groups: A (PFA) and B (PFB). PFA ependymomas are more common in infants and young children, and typically behave in a more aggressive manner than PFB ependymomas. Loss of H3K27 trimethylation by IHC is characteristic of PFA ependymomas, although genomic methylation profiling is the gold standard to differentiate PFA and PFB ependymomas, and should be used whenever possible.^{9,57-62}

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF BRAIN TUMOR PATHOLOGY: MOLECULAR MARKERS

The following molecular markers are often used by neuropathologists to facilitate characterization of gliomas and/or by neuro-oncologists to guide treatment decisions:

Ependymomas (continued)

• *ZFTA* Fusion

- ▶ Recommendation: Testing for *ZFTA* and *YAP1* fusions is recommended in the appropriate clinical context.
- ▶ Description: Ependymomas arising in the supratentorium often contain activating fusions of *ZFTA*. This leads to increased NF-kappa-B signaling and more aggressive behavior. This event is more common in children than in adults, and occurs only in the supratentorium, not the posterior fossa or spine.^{63,64}
- ▶ Detection: *ZFTA* fusion can be detected with RNA sequencing or a break-apart FISH probe set.⁶⁵
- ▶ Diagnostic value: Detection of *ZFTA* fusion is not required for the diagnosis of ependymoma, as this entity is still diagnosed by light microscopy.
- ▶ Prognostic value: *ZFTA* fusion-positive ependymomas are now a distinct entity in the WHO classification of CNS tumors, as this subset of ependymomas tends to be more aggressive than other supratentorial ependymomas, including those with *YAP1* fusions.^{1,63,64,66}

• *MYCN* Amplification

- ▶ A subset of spinal cord ependymomas show *MYCN* amplification. Such tumors tend to behave more aggressively, and are therefore now codified as SP-EPN-MYCN. As is often the case in other tumor types (eg, medulloblastoma), *MYCN* amplification is strongly associated with more aggressive behavior and worse prognosis. The difference in outcomes is distinct enough that a special diagnosis of “spinal ependymoma, *MYCN*-amplified” is now used in the new 5th WHO classification.¹

Medulloblastoma Molecular Subtyping

- Recommendation: Medulloblastoma testing should be referred to academic tertiary centers with expertise in this area.
- Description:
 - ▶ Medulloblastomas are WHO grade 4 tumors that predominantly arise from the cerebellum in pediatric patients, but can also occur in adults. The WHO committee on CNS tumors now recommends subclassification of these tumors into four distinct groups: i) WNT-activated; ii) SHH-

activated and *TP53*-mutant; iii) SHH-activated and *TP53*-wild type; and iv) non-WNT/non-SHH.^{1,67}

- Detection: Virtually all WNT-driven medulloblastomas will contain mutations in either *CTNNB1* or, less commonly, *APC* (the latter mutation may be germline if the patient has Turcot syndrome). Unlike in children, 50% of adult medulloblastomas with loss of 6q and positive nuclear catenin had no *CTNNB1* mutations, pointing towards the possibility of alternative mechanisms of WNT pathway activation in adult medulloblastoma.⁶⁸ Adult and pediatric medulloblastomas are genetically distinct and require different algorithms for molecular risk stratification. WNT-driven tumors will also usually contain monosomy 6. 6q loss is not confined to WNT in adults; it is also described in SHH and Group 4. Monosomy 6 is a specific marker for pediatric WNT, but not for adult WNT.⁶⁹ Nuclear immunoreactivity for beta-catenin is a very useful way to identify WNT medulloblastomas, in conjunction with *CTNNB1* sequencing and chromosome 6 FISH. Differentiating between WNT-activated, SHH-activated, and non-WNT/non-SHH tumors is best classified by DNA methylation arrays or an IHC panel composed of beta-catenin, *GAB1*, and *YAP1*. Because there are a variety of hotspots in *TP53*, gene sequencing is recommended in SHH-activated medulloblastomas.⁷⁰⁻⁷³
- Diagnostic value: None of the molecular markers associated with each medulloblastoma subtype is specific to medulloblastomas; the diagnosis of medulloblastoma is still made on the basis of light microscopy.
- Prognostic value: The most important aspect of medulloblastoma molecular diagnostics is that the WNT-activated subset has a markedly better prognosis relative to the other three subtypes, regardless of age at diagnosis. Among SHH-activated medulloblastomas, detection of *TP53* mutations is associated with more aggressive behavior, often in the setting of germline *TP53* mutations. Wildtype SHH-activated medulloblastomas have a variable course, and are uncommon in adults.⁷⁴⁻⁷⁶ Non-WNT/non-SHH medulloblastomas also show a variable course.^{1,67,74} WNT tumors have worse prognosis in adults compared to children based on retrospective data.⁶⁹ 6q loss and positive nuclear catenin have no clear prognostic role in adult medulloblastomas.

Note: All recommendations are category 2A unless otherwise indicated.

PRINCIPLES OF CANCER RISK ASSESSMENT AND COUNSELING

- See the following for a thorough discussion of how and when to consider testing, important elements of pre-test counseling, points to consider when using multi-gene testing, how tumor testing can inform germline testing, important elements in post-test counseling, and the importance of family communication:
 - ▶ Principles of Cancer Risk Assessment and Counseling ([NCCN Guidelines for Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic \[EVAL-A\]](#))
- For pedigree development, see Pedigree: First-, Second-, and Third-Degree Relatives of Proband ([NCCN Guidelines for Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic \[EVAL-B\]](#))
- When to consider genetic testing for (tuberous sclerosis, phakomatoses including *NF1*, and VHL syndrome):
 - ▶ For Li-Fraumeni syndrome, see [NCCN Guidelines for Genetic/Familial High-Risk Assessment: Breast, Ovarian, and Pancreatic](#)
 - ▶ For hereditary non-polyposis colorectal cancer (HNPCC or Lynch syndrome) and familial adenomatous polyposis (FAP)/attenuated FAP (AFAP) (for desmoid tumors), see [NCCN Guidelines for Genetic/Familial High-Risk Assessment: Colorectal](#)
 - ▶ For patients with personal/family history suggestive of other cancer predisposition syndromes, consider further genetics assessment

Note: All recommendations are category 2A unless otherwise indicated.

NCCN Categories of Evidence and Consensus	
Category 1	Based upon high-level evidence (≥1 randomized phase 3 trials or high-quality, robust meta-analyses), there is uniform NCCN consensus (≥85% support of the Panel) that the intervention is appropriate.
Category 2A	Based upon lower-level evidence, there is uniform NCCN consensus (≥85% support of the Panel) that the intervention is appropriate.
Category 2B	Based upon lower-level evidence, there is NCCN consensus (≥50%, but <85% support of the Panel) that the intervention is appropriate.
Category 3	Based upon any level of evidence, there is major NCCN disagreement that the intervention is appropriate.

All recommendations are category 2A unless otherwise indicated.

NCCN Categories of Preference	
Preferred intervention	Interventions that are based on superior efficacy, safety, and evidence; and, when appropriate, affordability.
Other recommended intervention	Other interventions that may be somewhat less efficacious, more toxic, or based on less mature data; or significantly less affordable for similar outcomes.
Useful in certain circumstances	Other interventions that may be used for selected patient populations (defined with recommendation).

All recommendations are considered appropriate.

Discussion This discussion corresponds to the NCCN Guidelines for Central Nervous System Cancers. Last updated: September 28, 2022.

Overview

In the year 2022, an estimated 25,050 people in the United States will be diagnosed with a malignant primary central nervous system (CNS) tumor, and these tumors will be responsible for approximately 18,280 deaths.¹ Though survival for CNS cancers has largely improved in recent decades, less improvement has been observed in older adults, due to higher incidence of glioblastoma in this population.²

The NCCN Guidelines for CNS Cancers focus on management of the following adult CNS cancers: glioma (WHO grade 1, oligodendroglioma [1p19q codeleted, *IDH*-mutant], *IDH*-mutant astrocytoma, glioblastoma), intracranial and spinal ependymomas, medulloblastoma, limited and extensive brain metastases, leptomeningeal metastases, non-AIDS-related primary CNS lymphomas (PCNSLs), metastatic spine tumors, meningiomas, and primary spinal cord tumors. These guidelines are updated annually to include new information or treatment philosophies as they become available. However, because this field continually evolves, practitioners should use all of the available information to determine the best clinical options for their patients.

Literature Search Criteria and Guidelines Update Methodology

Prior to the update of this version of the NCCN Guidelines for Central Nervous System Cancers, an electronic search of the PubMed database was performed to obtain key literature in the field of neuro-oncology, using the following search terms: {[brain OR spine OR spinal OR supratentorial OR cranial OR intracranial OR leptomeningeal] AND (cancer OR carcinoma OR tumor OR metastases OR lesion)] OR glioma OR astrocytoma OR oligodendroglioma OR glioblastoma OR ependymoma OR medulloblastoma OR (primary central nervous system lymphoma) OR meningioma}. The PubMed database was chosen because it remains the

most widely used resource for medical literature and indexes peer-reviewed biomedical literature.³

NCCN recommendations have been developed to be inclusive of individuals of all sexual and gender identities to the greatest extent possible. When citing data and recommendations from other organizations, the terms *men*, *male*, *women*, and *female* will be used to be consistent with the cited sources.

Principles of Management

Primary brain tumors are a heterogeneous group of neoplasms with varied outcomes and management strategies. Primary brain tumors range from pilocytic astrocytomas, which are very uncommon, noninvasive, and surgically curable, to glioblastoma, the most common malignant brain tumor in adults, which is highly invasive and virtually incurable. Brain metastases can also be quite variable. These patients may have one or dozens of brain metastases, and they may have a malignancy that is highly responsive or, alternatively, highly resistant to radiation therapy (RT) or systemic therapy. Moreover, patients with brain metastases may have rapidly progressive systemic disease or no systemic cancer at all. Because of this marked heterogeneity, the prognostic features and treatment options for primary and metastatic brain tumors must be carefully reviewed on an individual basis and sensitively communicated to each patient. In addition, these CNS tumors are associated with a range of symptoms such as seizures, fatigue, psychiatric disorders, impaired mobility, neurocognitive dysfunction, difficulty speaking, and short-term memory problems, as well as complications such as intracerebral edema, endocrinopathies, and venous thromboembolism that can seriously impact patients' quality of life.

The involvement of an interdisciplinary team, including neurosurgeons, radiation oncologists, medical oncologists, neurologists, and

neuroradiologists, is a key factor in the appropriate management of these patients. For any type of malignant brain tumors, the NCCN Panel strongly recommends brain tumor board for multidisciplinary review of each patient's case once the pathology report is available. Further discussion of multidisciplinary care and allied services, as well as guidelines on medical management of various disease complications, can be found in *Principles of Brain and Spine Tumor Management* in the algorithm.

Treatment Principles

The information contained in the algorithms and principles of management sections in the NCCN Guidelines for CNS Cancers are designed to help clinicians navigate through the complex management of patients with CNS tumors. Several important principles guide surgical management and treatment with RT and systemic therapy for adults with brain tumors.

Regardless of tumor histology, neurosurgeons generally provide the best outcome for their patients if they remove as much tumor as safely possible (ideally achieving a gross total resection [GTR]) and thereby provide sufficient representative tumor tissue to ensure an accurate diagnosis. Decisions regarding aggressiveness of surgery for primary and metastatic brain tumors are complex and depend on the: 1) age and performance status (PS) of the patient; 2) proximity to “eloquent” areas of the brain; 3) feasibility of decreasing the mass effect with aggressive surgery; 4) resectability of the tumor (including the number and location of lesions); and 5) time since last surgery in patients with recurrent disease.⁴ Further discussion can be found in the *Principles of Brain Tumor Surgery* in the algorithm. It is recommended to consult neurosurgeons with extensive experience in the management of intracranial and spine neoplasms.

Surgical options include stereotactic biopsy, open biopsy, subtotal resection (STR), or GTR. The pathologic diagnosis is critical and may be difficult to accurately determine without sufficient tumor tissue. Review of

the tumor tissue by an experienced neuropathologist is highly recommended. The *Principles of Brain Tumor Pathology* describe guiding principles for diagnosis of CNS tumor pathology, given the addition of molecular parameters for accurately diagnosing primary brain tumors in the 2016 WHO classification of CNS tumors⁵, which were further expanded upon in the 2021 WHO classification.⁶

Radiation oncologists use several different treatment modalities to treat patients with primary brain tumors. Standard fractionated external beam RT (EBRT) is the most common approach and is administered within a limited field (covering tumor or surgical cavity and a small margin of adjacent brain tissue). Hypofractionated radiation is an appropriate option for select patients (ie, older adults and patients with a poor PS). For the treatment of brain metastases, whole-brain RT (WBRT) and stereotactic radiosurgery (SRS) are primarily used. The dose of RT administered varies depending on the type of tumor, as discussed in the *Principles of Radiation Therapy for Brain and Spinal Cord*.

Regarding systemic therapy, multiple options exist for treating brain tumors. Alkylating agents remain the most effective chemotherapy for primary brain tumors. For brain metastases, choice of systemic therapy should be based on an agent's activity against the primary tumor and the ability of the agent to cross the blood-brain barrier (BBB). Standard systemic therapy options for each tumor subtype are listed in the *Principles of Brain and Spinal Cord Tumor Systemic Therapy*; however, since the efficacy of these chemotherapies is limited and better treatments for brain tumors are needed, enrollment in a clinical trial is the preferred treatment for eligible patients.

Gliomas

The NCCN Guidelines for CNS Cancers include recommendations for management of the following adult gliomas:⁶

- WHO Grade 1: pilocytic astrocytoma, pleomorphic xanthoastrocytoma, ganglioglioma, and subependymal giant cell astrocytoma (SEGA)
- Oligodendrogliomas (*IDH*-mutant, 1p19q codeleted)
- *IDH*-mutant astrocytoma
- Glioblastoma

Molecular Profiling for Gliomas

Integrated histopathologic and molecular characterization of gliomas, as per WHO classification,⁶ should be standard practice. Molecular/genetic characterization complements standard histologic analysis, providing additional diagnostic and prognostic information that improves diagnostic accuracy and aids in treatment selection and management decision-making. Histopathologic and molecular analysis of CNS tumors is limited by inter-observer discrepancies and surgical sampling that doesn't always capture all relevant diagnostic features in morphologically heterogeneous tumors.

Updated Classification of Gliomas Based on Histology and Molecular Features

In 2016, the WHO classification for grade 2–3 gliomas was revised as follows: 1) oligodendrogliomas were gliomas that have whole arm 1p/19q codeletion and *IDH1* or *IDH2* (together referred to as “*IDH*”) mutation (unless molecular data were not available and could not be obtained, in which case designation was based on histology with appropriate caveats); 2) anaplastic gliomas were further subdivided according to *IDH* mutation status; and 3) oligoastrocytoma was no longer a valid designation unless molecular data (1p/19q codeletion and *IDH* mutation status) were not available and could not be obtained.⁵ Such tumors were described as “oligoastrocytoma, not otherwise specified (NOS)” to indicate that the

characterization of the tumor was incomplete. Very rare cases of concurrent, spatially distinct oligodendroglioma (1p/19q codeleted) and astrocytoma (1p/19q intact) components in the same tumor could also be labeled oligoastrocytoma.⁵ Correlations between the molecularly defined 2016 WHO categories and the histology-based 2007 WHO categories were limited and varied across studies.^{7–10} Thus, the change from 2007 WHO to 2016 WHO reclassified a large proportion of gliomas.

The fifth edition of the WHO classification of CNS tumors was published in 2021.^{6,11} In this newest classification, adult diffuse gliomas are subsumed within a supercategory of gliomas and glioneuronal tumors, and are split into three subtypes: 1) *IDH*-mutant astrocytoma; 2) oligodendroglioma, 1p/19q-codeleted and *IDH*-mutant; and 3) glioblastoma, *IDH* wild-type. WHO grades are now further specified for select CNS tumors, including diffuse gliomas. Specifically, *IDH*-mutant astrocytoma can be grade 2, 3, or 4. Oligodendroglioma (1p/19q-codeleted and *IDH*-mutant) can be grade 2 or 3. Glioblastoma, *IDH* wild-type, can only be grade 4. This updated classification further takes into account the importance of molecular data for accurately diagnosing CNS tumors.⁶

Multiple independent studies on gliomas have conducted genome-wide analyses evaluating an array of molecular features, including DNA copy number, DNA methylation, and mutations, in large populations of patients with grade 2–4 tumors.^{9,12,13} Unsupervised clustering analyses, an unbiased method for identifying molecularly similar tumors, have been used to identify subgroups of gliomas with distinct molecular profiles.^{9,12,13} Remarkably, further analysis has shown that these molecular subgroups could be distinguished based on only a handful of molecular features, including *IDH* mutation and 1p/19q codeletion, biomarkers independently verified by numerous studies as hallmarks for distinguishing molecular subgroups in grade 2–3 gliomas.^{7–10,13–19} The unsupervised clustering analysis published by the Cancer Genome Atlas Research Network

supports the idea that the majority of grade 2–3 tumors can be divided into three molecular subtypes: 1) mutation of *IDH* with 1p/19q codeletion; 2) *IDH*-mutant with no 1p/19q codeletion; and 3) no mutation of *IDH* (ie, *IDH* wild-type).⁹ Multiple studies have shown that the 1p/19q codeletion is strongly associated with *IDH* mutations, such that true whole-arm 1p/19q codeletion in *IDH* wild-type tumors is extremely rare.^{7,8,16,20,21} In a tumor that is equivocal, the presence of an *IDH* mutation indicates at least a grade 2 diffusely infiltrative glioma.²² Some *IDH*-mutant diffusely infiltrative astrocytomas develop the traditional grade 4 histologic features of necrosis and/or microvascular proliferation, which suggest more aggressive behavior and worse prognosis, but still not as severe as *IDH* wild-type glioblastoma. Such tumors are now referred to as astrocytoma, *IDH*-mutant, WHO grade 4, to distinguish them from *IDH* wild-type glioblastoma.^{23,24} Grade 1 non-infiltrative gliomas do not have *IDH* mutations.²²

Other mutations commonly detected in gliomas can have diagnostic and prognostic value, such as those involving the histone chaperone protein, *ATRX*, which is most often found in grade 2–3 gliomas and secondary glioblastomas.^{25,26} *ATRX* mutation is robustly associated with *IDH* mutations, and this combination, along with *TP53* mutations, is diagnostic of astrocytoma.²⁷ In contrast, *ATRX* mutation is nearly always mutually exclusive with 1p/19q codeletion. Since loss of normal nuclear *ATRX* immunostaining is a fairly reliable indicator of an *ATRX* mutation, an *IDH* mutant glioma that has loss of normal nuclear *ATRX* immunostaining is much more likely to be an astrocytoma than an oligodendroglioma.

Mutations in the promoter region of the *telomerase reverse transcriptase* (*TERT*) gene occur frequently in *IDH* wild-type glioblastomas and *IDH* mutant, 1p/19q codeleted oligodendrogliomas.^{28,29} Absence of *TERT* promoter mutation, coupled with *IDH* mutation and lack of 1p/19q codeletion, is indicative of astrocytoma. Some *IDH* wild-type diffusely

infiltrative astrocytomas lack the histologic features of glioblastoma (necrosis and/or microvascular proliferation) but have one or more molecular hallmarks of glioblastoma, including the following: *EGFR* amplification; gain of chromosome 7 and loss of chromosome 10; and *TERT* promoter mutation. In such cases, the tumor can still be diagnosed as glioblastoma, *IDH* wild-type, WHO grade 4. These tumors have similar clinical outcomes as typical histologic grade 4 *IDH* wild-type glioblastomas, so they may be managed accordingly.^{22,24} Similarly, the 2021 updated WHO classification of CNS tumors also now includes *CDKN2A/B* homozygous deletion as evidence of grade 4 status in *IDH* mutant astrocytomas, even if such astrocytomas lack necrosis and microvascular proliferation.^{6,23,30-33}

H3K27M mutations in the histone-encoding *H3-3A* gene are mostly found in diffuse midline gliomas in both children and adults.³⁴ Patients with these H3K27M mutated gliomas tend to have a very poor prognosis regardless of histologic appearance, so they are classified as WHO grade 4.^{34,35} Another variant in *H3-3A*, resulting in a G34V (or R) mutation in histone 3.3, is characteristic of some diffusely infiltrative gliomas arising not in the midline, but in the cerebral hemispheres. These gliomas tend to occur in children and younger adults and are *IDH* wild-type, but still have mutations in *ATRX* and *TP53*. Thus, the 5th edition of the WHO classification calls these tumors “Diffuse hemispheric glioma, H3.3 G34-mutant, WHO grade 4.”⁶ H3K27M immunopositivity is associated with loss of histone trimethylation immunostaining in diffuse midline gliomas.³⁶⁻⁴⁰ The presence of a histone mutation can be considered solid evidence of an infiltrative glioma, which is often helpful in small biopsies of midline lesions that may not be fully diagnostic with light microscopy and/or do not clearly look like infiltrative gliomas.^{34,41} Both kinds of *H3-3A* mutant gliomas are now subsumed by the 2021 WHO classification under “pediatric-type diffuse high grade gliomas,” even if such tumors arise in adults.^{6,11} Histone-driven

gliomas are no longer called glioblastomas, as that term is now reserved exclusively for *IDH* wild-type gliomas meeting the criteria discussed above.

Prognostic Relevance of Molecular Subgroups in Glioma

Numerous large studies of patients with brain tumors have determined that, among WHO grade 2–3 gliomas, 1p/19q codeletion correlates with greatly improved progression-free survival (PFS) and overall survival (OS).^{8,13,14,42-44} Likewise, the presence of an *IDH* mutation is a strong favorable prognostic marker for OS in grade 2–3 gliomas.^{9,16} Analyses within single treatment arms showed that the *IDH* status is prognostic for outcome across a variety of postoperative adjuvant options. For example, in the NOA-04 phase III randomized trial, *IDH* mutation was associated with improved PFS, longer time to treatment failure, and extended OS in each of the three treatment arms: standard RT (n = 160); combination therapy with procarbazine, lomustine, and vincristine (PCV; RT upon progression; n = 78); and temozolomide (TMZ; RT upon progression; n = 80).⁴³

Multiple independent studies, covering multiple grades and histology-based subtypes of gliomas,^{9,13,42} as well as smaller studies limited to 1 to 2 grades or histologic subtypes,^{8,45-47} have consistently supported the subdivision of gliomas by molecular subtype (eg, by *IDH* and 1p/19q status) as recommended by the WHO 2021 CNS tumor classification, as this yields greater prognostic separation than subdivision by histology alone. Multiple studies have shown that, among patients with grade 2–3 gliomas, the *IDH*-mutant plus 1p/19q-codeletion group (ie, oligodendroglioma) has the best prognosis, followed by *IDH*-mutant without 1p/19q codeletion (ie, astrocytoma); the *IDH* wild-type group (ie, glioblastoma) has the worst prognosis.^{8-10,42-44} Analyses within single treatment arms have confirmed this trend in prognosis across a variety of postoperative adjuvant treatment options.^{8,43,44,47} *TERT* promoter mutations in patients with high-grade *IDH* wild-type glioma are associated

with shorter OS, compared to *IDH* wild-type tumors without a *TERT* promoter mutation.^{10,29,48} However, a multivariable analysis of data from 291 patients with *IDH*-mutant, 1p/19q-codeleted oligodendrogliomas showed that absence of a *TERT* promoter mutation was associated with worse OS, compared to those with *TERT* promoter-mutant oligodendrogliomas (HR, 2.72; 95% CI, 1.05–7.04; *P* = .04).⁴⁹ An analysis of an older database, which included 271 patients with WHO grade 2 glioma who were diagnosed according to the 2007 WHO classification, showed that *IDH*-mutant gliomas were associated with increased OS and better response to TMZ than *IDH* wild-type gliomas.⁸

MGMT (O-6-methylguanine-DNA methyltransferase) is a DNA repair enzyme that can cause resistance to DNA-alkylating drugs.⁵⁰ MGMT promoter methylation is associated with better survival outcomes in patients with high-grade glioma and is a predictive factor for response to treatment with alkylating chemotherapy such as TMZ or lomustine,^{35,51-53} even in older adult patients.^{54,55} *IDH* mutations are commonly associated with MGMT promoter methylation.¹⁰ Tumors with H3K27M mutations are far less likely to be MGMT promoter methylated³⁴ and are associated with even worse prognosis than *IDH* wild-type glioblastomas.^{41,56} Patients whose hemispheric high-grade gliomas contain *H3-3A* G34 mutations, however, have relatively higher rates of MGMT promoter methylation than H3K27M diffuse midline gliomas, and do not have a worse prognosis than other *IDH* wild-type glioblastomas.^{41,57}

Most WHO grade 1 pilocytic astrocytomas in pediatric patients contain *BRAF* fusions or, less commonly, *BRAF* V600E mutations, especially those arising in the posterior fossa; such tumors are rarely high grade.⁵⁸ *BRAF* fusion is associated with better prognosis in pediatric low-grade astrocytoma.⁵⁸⁻⁶⁰ The likelihood of a *BRAF* fusion in a pilocytic astrocytoma decreases with age.⁵⁸ *BRAF* V600E is present in 60% to 80% of pleomorphic xanthoastrocytomas, although it has also been found in

many other low-grade gliomas, such as gangliogliomas and dysembryoplastic neuroepithelial tumors,^{35,58,61} as well as less than 5% of glioblastomas (especially epithelioid glioblastoma).⁶² Pediatric low-grade glioma with *BRAF* fusions tend to be indolent with occasional recurrence, but only rarely do they progress to cause death.^{59,60,63} Retrospective studies have shown that *BRAF* V600E may be associated with increased risk of progression in pediatric low-grade gliomas,⁶⁴ but one study found that this association was not quite statistically significant ($N = 198$; $P = .07$).⁶⁰ Some studies have shown that tumors with a *BRAF* V600E mutation may respond to *BRAF* inhibitors such as vemurafenib,⁶⁵⁻⁶⁷ but ongoing trials will further clarify targeted treatment options in the presence of a *BRAF* fusion or V600E mutation (eg, NCT03224767, NCT03430947). *BRAF* fusion and/or mutation testing are clinically indicated in patients with low-grade glioma.

NCCN Molecular Testing Recommendations for Glioma

Recommendations for molecular testing of glioma tumors are provided in the *Principles of Brain Tumor Pathology* section in the algorithm. Based on studies showing that *IDH* status is associated with better prognosis in patients with grade 2–3 glioma,^{20,42,43,68} the panel recommends *IDH* mutation testing in patients with glioma. Immunohistochemistry (IHC) can detect the most common (canonical) *IDH* mutation, *IDH1* R132H. However, sequencing must be done to detect non-canonical *IDH1* mutations (eg, *IDH1* R132C) and *IDH2* mutations. Since *ATRX* and *IDH* mutations frequently co-occur, a lack of *ATRX* immunostaining, coupled with negative R132H immunostaining for *IDH1* in a glioma, should trigger screening for such non-canonical *IDH* mutations.²⁷

Testing for 1p/19q codeletion is essential for the diagnosis of oligodendroglioma. However, since true whole-arm 1p/19q codeletion is essentially nonexistent in the absence of an *IDH* mutation,^{20,21,69} 1p/19q testing is not necessary in tumors that are definitely *IDH* wild-type, and

tumors without an *IDH* mutation should not be regarded as truly 1p/19q-codeleted, even when results suggest otherwise. Mutation testing for *ATRX* and *TERT* promoter are also recommended, given the diagnostic value of these mutations.^{25,27-29} *IDH*-mutated gliomas that do not show loss of nuclear *ATRX* immunostaining should be strongly considered for 1p/19q testing, even if not clearly oligodendroglial by histology. *H3-3A* and *HIST1H3B* sequencing and *BRAF* fusion and/or mutation testing may be carried out as clinically indicated. A K27M histone-specific antibody is available, but it can be difficult to interpret.⁷⁰

Grade 3–4 gliomas should undergo testing for *MGMT* promoter methylation, since *MGMT* promoter-methylated tumors typically respond better to alkylating chemotherapy, compared to unmethylated tumors.^{51,54,55,71} There are several accepted methods for testing *MGMT* promoter methylation. Methylation-specific PCR is the assay that has the most validation in clinical trials,⁷² but a 2012 study including 100 patients with glioblastoma treated with TMZ suggested that pyrosequencing may be the best prognostic stratifier.⁷³ Molecular testing of glioblastomas is encouraged by the panel, as patients with a detected driver mutation (eg, *BRAF* V600E mutation or *NTRK* fusion) may be treated with a targeted therapy on a compassionate use basis, and these tests improve diagnostic accuracy and prognostic stratification. Detection of genetic or epigenetic alterations could also expand clinical trial options for a brain tumor patient.

Low-Grade Gliomas

Low-grade gliomas (ie, pilocytic and diffusely infiltrative astrocytomas, oligodendrogliomas) are a diverse group of relatively uncommon malignancies classified as grade 1 and 2 under the WHO grading system.⁶ Low-grade gliomas comprise approximately 5% to 10% of all CNS tumors.⁷⁴ Seizure is a common symptom (81%) of low-grade gliomas, and is more frequently associated with oligodendrogliomas.^{75,76} The median duration from onset of symptoms to diagnosis ranges from 6 to 17 months.

Grade 1 Gliomas

Diffuse astrocytomas are poorly circumscribed and invasive, and most gradually evolve into higher-grade astrocytomas. Although these were traditionally considered benign, they can behave aggressively and will undergo anaplastic transformation within 5 years in approximately half of patients.^{77,78} The most common non-infiltrative astrocytomas are pilocytic astrocytomas. Other grade 1 gliomas in which treatment recommendations are included in the NCCN Guidelines for CNS Cancers are pleomorphic xanthoastrocytoma, SEGA, and ganglioglioma, though these grade 1 gliomas are uncommon. Pleomorphic xanthoastrocytomas are associated with favorable prognosis,^{79,80} though mitotic index is associated with survival outcomes.^{80,81} Gangliogliomas are commonly located in the temporal lobe, and the most significant predictors of survival are low tumor grade and younger age.⁸²

SEGAs are typically located at the caudothalamic groove adjacent to the foramen of Monro. Though they are generally slow-growing and histologically benign, they can also be associated with manifestations such as hydrocephalus, intracranial pressure, and seizures.⁸³ SEGAs can be distinguished from subependymal nodules by their characteristic serial growth.⁸⁴ These tumors occur in 5% to 20% of individuals with tuberous sclerosis complex (TSC).⁸⁵⁻⁸⁷

Treatment

Grade 1 gliomas are usually curable by surgery alone. Indication for treatment of SEGAs is based on development of new symptoms or radiologic evidence of tumor growth.⁸⁴ Though surgery is sometimes a recommended option for SEGAs, many are in an area not amenable to resection, and recurrence may occur following resection.^{88,89} Surgery may pose risks because of the frequent location of SEGAs near the foramen of Monro, but in specialized centers, morbidity is acceptable, and surgical mortality is extremely low.⁹⁰

There is some evidence that BRAF inhibitors, as well as a BRAF/MEK inhibitor combination, may be used for treatment of low-grade gliomas that are BRAF mutated. The phase II VE-BASKET study showed that vemurafenib was efficacious in BRAF-mutated low-grade gliomas, particularly PXA, with an overall response rate (ORR) of 42.9% (n = 7), median PFS of 5.7 months, and median OS not reached.⁶⁷ Another phase II trial including 13 patients with BRAF-mutated low-grade glioma showed that dabrafenib/trametinib was associated with an ORR of 69%.⁹¹ Case reports have demonstrated clinical activity for the combination BRAF/MEK inhibitor dabrafenib/trametinib in patients with *BRAF* V600E mutant glioma.^{92,93}

Reducing or stabilizing the volume of SEGAs through systemic therapy has been investigated. A phase III trial showed that 78 patients with SEGA and TSC who received everolimus, an mTOR inhibitor, had at least a 50% reduction in tumor volume, compared to 39 patients who received a placebo (35% vs. 0%; $P < .001$), and 6-month PFS was 100% versus 86%, respectively ($P < .001$).⁹⁴ Analyses from a long-term follow-up showed that median duration of response was not reached, with response duration ranging from 2.1 months to 31.1 months.⁹⁵ Tumor volume reduction rates of 30% and 50% were maintained in patients in the everolimus arm for more than 3 years. This regimen was generally well-tolerated, with the most frequently reported grade 3 or 4 adverse events being stomatitis (8%) and pneumonia (8%). Everolimus has also been investigated in a phase II trial including 58 patients with recurrent grade 2 gliomas, with a 6-month PFS rate of 84%.⁹⁶ Medical therapy of SEGA, while effective, is a long-term commitment, unless it is being used short-term to facilitate surgical resection. Once mTOR inhibitor therapy is stopped, lesions typically recur, usually within several months, and eventually reach pretreatment volume. The lesions will continue to grow unless therapy is reintroduced. Most patients tolerate long-term therapy with mTOR inhibitors quite well.⁹⁷

NCCN Recommendations

When possible, maximal safe resection is recommended for grade 1 gliomas, and the actual extent of resection should be documented with a T2-weighted or FLAIR MRI scan within 48 hours after surgery. Patients may be observed following surgery. If incomplete resection or biopsy, or if surgery was not feasible, then RT may be considered if there is significant tumor growth or if neurologic symptoms are present or develop. A BRAF/MEK inhibitor combination may be used for patients with *BRAF* V600E mutant low-grade glioma. TRK inhibitors larotrectinib and entrectinib may be used for patients with *NTRK* gene fusion-positive tumors.^{98,99} Treatment with an mTOR inhibitor (eg, everolimus) should be considered for patients with SEGA,^{94,95} though institutional expertise and patient preference should guide treatment decision-making for these rare tumors.⁸⁴

Grade 2 Oligodendroglioma (IDH-mutant, 1p19q codeleted) and IDH-mutant Astrocytoma

Radiographically, low-grade oligodendrogliomas appear well demarcated, occasionally contain calcifications, and do not often enhance with contrast. In histology, the typical “fried egg” appearance of these tumors is evident as a fixation artifact in paraffin but not in frozen sections. Survival rates tend to be better in oligodendrogliomas than in other gliomas (ie, diffuse astrocytomas, anaplastic astrocytomas, glioblastoma).⁷⁴

Factors prognostic for PFS or OS in patients with grade 2 gliomas include age, tumor diameter, tumor crossing midline, neurologic status or PS prior to surgery, and the presence of certain molecular markers (see section above on *Molecular Profiling for Gliomas*).^{8,14,100-105} For example, *IDH1/2* mutation is associated with a favorable prognosis in patients with grade 2 and 3 gliomas,^{9,10,43} supporting the emerging idea that molecular analysis should play a much larger role in treatment decision-making, relative to histopathology.⁷⁶

Treatment Overview

Surgery

Surgery remains an important diagnostic and therapeutic modality. The primary surgical goals are maximal safe resection to delay progression and improve survival, relief of symptoms, and provision of adequate tissue for a pathologic diagnosis and grading. Needle biopsies are often performed when lesions are in deep or critical regions of the brain. Biopsy results can be misleading, because gliomas often have varying degrees of cellularity, mitoses, or necrosis from one region to another; thus, small samples can provide erroneous histologic grade or diagnosis.^{106,107}

Surgical resection plays an important role in the management of low-grade gliomas. A systematic review showed that GTR was significantly associated with decreased mortality and lower risk of disease progression up to 10 years after treatment, compared to STR.¹⁰⁸ Because these tumors are relatively uncommon, published series generally include patients treated for decades, which introduces additional variables. For example, the completeness of surgical excision was based on the surgeon’s report in older studies. This approach is relatively unreliable when compared with assessment by modern postoperative imaging studies. Furthermore, many patients also received RT, and thus the net effect of the surgical procedure on outcome is difficult to evaluate. Two meta-analyses including studies of primary low-grade gliomas show that extent of resection is a significant prognostic factor for PFS and/or OS.^{109,110} Maximal safe resection may also delay or prevent malignant progression¹¹⁰⁻¹¹² and recurrence.¹¹³ Patients who undergo an STR, open biopsy, or stereotactic biopsy are, therefore, considered to be at higher risk for progression. GTR is also associated with improved seizure control compared to STR.¹¹⁰

Biological considerations also favor an attempt at a complete excision of a low-grade glioma. First, the tumor may contain higher-grade foci, which

may not be reflected in a small specimen. Second, complete excision may decrease the risk of future dedifferentiation to a more malignant tumor.¹¹⁴ Third, removal of a large tumor burden may enhance the benefit of RT. As a result of these considerations, the general recommendation for treating a low-grade glioma is to first attempt as complete an excision of tumor as possible (based on postsurgical MRI verification) without compromising function. However, for tumors that involve eloquent areas, a total removal may not be feasible, and an aggressive approach could result in neurologic deficits. Residual tumor volume may also be a prognostic factor, with a randomized single institution study showing that the OS benefit of maximal safe resection was limited to patients with a residual tumor volume less than 15 cm³.¹¹⁵

Adjuvant Therapy

A large meta-analysis, including data from phase 3 trials (EORTC 22844 and 22845,^{116,117} and NCCTG 86-72-51¹⁰³), confirmed that surgery followed by RT significantly improves PFS but not OS in patients with low-grade gliomas.¹¹⁸ Early versus late postoperative RT did not significantly affect OS, however, suggesting that observation is a reasonable option for some patients with newly diagnosed gliomas.¹¹⁷

Final results of a phase 3 randomized clinical trial, RTOG 9802, which assessed the efficacy of adjuvant RT versus RT followed by 6 cycles of PCV in patients with newly diagnosed supratentorial WHO grade 2 gliomas and at least one of two risk factors for disease progression (STR or age ≥40 years)¹¹⁹ showed significant improvements in both PFS and OS with the addition of PCV.¹²⁰ The median survival time increased from 7.8 years to 13.3 years ($P = .02$), and the 10-year survival rate increased from 41% to 62%. It is important to note, however, that roughly three-quarters of the study participants had a Karnofsky Performance Status (KPS) score of 90 to 100, and the median age was around 40 years.¹¹⁹ Exploratory analyses based on histologic subgroups showed a statistically

significant improvement in OS for all subgroups except for patients with astrocytoma.¹²⁰ Given that the study participants treated with PCV after RT experienced a significantly higher incidence of grade 3 or 4 adverse events (specifically neutropenia, gastrointestinal disorder, and fatigue),^{119,120} PCV may be difficult to tolerate in patients who are older or with poor PS. A retrospective subgroup analysis suggests that the survival benefit with the addition of PCV was seen only in *IDH*-mutant tumors; patients with oligodendrogliomas benefited more than those with astrocytomas; the *IDH* wild-type subgroup did not appear to benefit from the chemotherapy.¹²¹

Combined treatment with RT plus TMZ is supported by a phase 2 multicenter trial (RTOG 0424) in patients with supratentorial WHO grade 2 tumors and additional risk factors (ie, age ≥40 years, astrocytoma, bi-hemispherical, tumor diameter ≥6 cm, neurologic function status >1).^{122,123} However, since the historical controls included patients treated in an earlier time period using different RT protocols, prospective controlled trials are needed to determine whether treatment with TMZ concurrently and following RT is as efficacious as PCV following radiation. There are currently no phase III data to support the use of RT and TMZ over RT and PCV for the treatment of patients with newly diagnosed, high-risk, low-grade glioma. The phase 3 randomized EORTC 22033-26033 trial showed that PFS is not significantly different for adjuvant RT versus dose-dense TMZ in patients with resected or biopsied supratentorial grade 2 glioma and more than one risk factor (N = 477).¹⁵ However, analyses of OS have not yet been reported for this trial.

Radiation Therapy

When RT is given to patients with low-grade gliomas, it is administered with restricted margins. A T2-weighted (occasionally enhanced T1) and/or FLAIR MRI scan is the best means for evaluating tumor extent, because these tumors enhance weakly or not at all. The clinical target volume

(CTV) is defined by the FLAIR or T2-weighted tumor with a 1- to 2-cm margin. Every attempt should be made to decrease the RT dose outside the target volume. This can be achieved with 3-dimensional (3D) planning or intensity-modulated RT (IMRT), with improved target coverage and normal brain/critical structure sparing often shown with IMRT.^{124,125} The recommended dosing for postoperative RT is based on results from two phase 3 randomized trials showing that higher dose RT had no significant effect on OS or time to progression,^{103,116} and on several retrospective analyses showing similar results.^{102,104,126} Because higher doses offer no clear advantages, the CNS Panel recommends lower-dose RT (45–54 Gy) for treatment of low-grade gliomas (grades 1 and 2), including high-risk cases. However, *IDH* wild-type low-grade gliomas have similar survival only slightly better than *IDH* wild-type glioblastomas.⁹ Therefore, an RT dose of 59.4 to 60 Gy may be considered for this subset of patients with low-grade glioma. Preliminary data suggest that proton therapy could reduce the radiation dose to developing brain tissue and potentially diminish toxicities without compromising disease control.¹²⁷

Recurrent or Progressive Disease

Though the survival impact is unclear, surgery for recurrent disease in patients with low-grade glioma may reduce symptoms, provide tissue for evaluation, and potentially allow for molecular characterization of the tumor.¹²⁸⁻¹³¹ Maximal safe resection could play an important role for optimizing survival outcomes; a threshold value is unknown, but >90% extent of resection is suggested.¹³¹ For patients without previous RT, results of the RTOG 9802 trial^{119,120} support use of chemotherapy with RT. Data from phase II trials inform recommendations for chemotherapy treatment of patients with recurrent or progressive low-grade glioma.¹³²⁻¹³⁸ Patients should be enrolled in clinical trials evaluating systemic therapy options.

NCCN Recommendations

Primary and Adjuvant Treatment

For treatment recommendations for newly diagnosed WHO grade 2 gliomas (oligodendroglioma [*IDH*-mutant, 1p19q codeleted] and *IDH*-mutant astrocytoma), the panel used the RTOG 9802^{119,120} criteria for determining if a patient is considered to be at low or high risk for tumor progression: patients are categorized as being at low risk if they are ≤40 years and underwent a GTR; high-risk patients are >40 years of age and/or underwent an STR. However, the panel acknowledges that other prognostic factors have been used to guide adjuvant treatment choice in other studies of patients with low-grade glioma,¹³⁹ such as tumor size, presence of neurologic deficits, loss of *CDKN2A* homozygous deletion, and the *IDH* mutation status of the tumor.^{15,100} If these other risk factors are considered, and treatment of a patient is warranted, then the panel recommends that the patient be treated as high-risk.

Patients with low-risk WHO grade 2 glioma may be observed following surgery. Close follow-up is essential as over half of these patients will develop tumor progression within 5 years.¹⁰⁵ Following surgery, RT followed by PCV is a category 1 recommendation for patients with WHO grade 2 glioma who are considered to be at high risk for tumor progression, based on the practice-changing results from the RTOG 9802 study,^{119,120} as discussed above. When PCV is indicated, carmustine may be substituted for lomustine. There is currently a lack of prospective randomized phase 3 data for the use of radiation and TMZ in patients with low-grade glioma, but interim data from the phase III CATNON trial illustrate that there is a benefit from adjuvant TMZ in patients with newly diagnosed 1p19q non-codeleted WHO grade 3 gliomas.¹⁴⁰ Therefore, RT followed by adjuvant TMZ is a category 2A option. Data from EORTC and NCIC studies, which included patients with glioblastoma, support RT with concurrent and adjuvant TMZ as an evidence-based regimen.^{141,142}

Therefore, this is also a category 2A option. Because PCV is generally a

more difficult chemotherapy regimen to tolerate than TMZ, it may be reasonable to treat an elderly patient or a patient with multiple comorbidities with RT and TMZ instead of RT and PCV, but there are currently no data to show that doing so would result in similar improvement in OS.

Since the design of RTOG 9802^{119,120} did not address whether all patients should be treated with RT followed by PCV immediately after a tissue diagnosis (an observation arm was not included for patients with high-risk glioma [defined as >40 years of age and/or underwent an STR]¹⁰⁵ in the study), observation after tissue diagnosis may be a reasonable option for some patients with high-risk WHO grade 2 glioma who are neurologically asymptomatic or who have stable disease. However, close monitoring of such patients with brain MRI is important. Results from EORTC 22845, which showed that treatment with RT at diagnosis versus at progression did not significantly impact OS, provide rationale for observation in select cases with low-grade gliomas as an initial approach, deferring RT.¹¹⁷ Long-term toxicity from radiation needs to be a consideration, especially for young patients with 1p19q codeletion, for whom there is slightly higher risk of radiation necrosis.¹⁴³

Recurrence

At the time of recurrence, surgery is recommended if resectable disease is present. Because recurrence on neuroimaging may be confounded by treatment effects, biopsy of unresectable disease should be considered to confirm recurrence. There is a propensity for low-grade gliomas to transform to higher-grade gliomas over time. Therefore, documenting the histopathologic transformation of a low-grade glioma to a high-grade glioma may also enable patients to have clinical trial opportunities, since most clinical trials in the recurrent setting are for patients with high-grade gliomas. Moreover, sampling of tumor tissue to confirm recurrence is

encouraged to obtain tissue for next-generation sequencing, the results of which may inform treatment selection and/or clinical trial eligibility.

Surgery for recurrent low-grade disease may be followed by the following treatment options for patients previously treated with fractionated EBRT: 1) systemic therapy including clinical trials; 2) consideration of reirradiation with or without systemic therapy; and 3) palliative/best supportive care. Reirradiation is a good choice if the new lesion is outside the target of previous RT or if the recurrence is small and geometrically favorable. For patients with low-risk features for whom GTR was achieved, observation with no further treatment may be considered.

Based on the strength of the RTOG 9802 results,^{119,120} RT with systemic therapy is a treatment option for patients with recurrent or progressive low-grade gliomas who have not had prior RT. Options include RT + adjuvant PCV, RT + adjuvant TMZ, and RT + concurrent and adjuvant TMZ. RT alone is generally not the preferred treatment option except in select cases, such as a patient with a poor PS, or who does not want to undergo systemic therapy treatment. Systemic therapy alone (eg, TMZ, PCV, carmustine/lomustine) is also a treatment option for these patients, though this is a category 2B option based on less panel consensus.

High-Grade Gliomas (Including Glioblastoma)

High-grade gliomas (defined as WHO grade 3 and 4 gliomas) account for more than half of all malignant primary tumors of the CNS.² Whereas the prognosis for glioblastoma (grade 4 glioma) is grim (5-year survival rates around 6%, with higher rates among younger age groups), outcomes for WHO grade 3 gliomas are typically better, depending on the molecular features of the tumor (see *Molecular Profiling for Gliomas: Prognostic Relevance of Molecular Subgroups in Glioma* above in this Discussion).⁷⁴ Challenges regarding treatment of glioblastoma include the inability of

most systemic therapy agents to penetrate the BBB and heterogeneity among genetic drivers.¹⁴⁴

High-grade astrocytomas diffusely infiltrate surrounding tissues and frequently cross the midline to involve the contralateral brain. Patients with these neoplasms often present with symptoms of increased intracranial pressure, seizures, or focal neurologic findings related to the size and location of the tumor and associated vasogenic edema. High-grade astrocytomas usually do not have associated hemorrhage or calcification but can produce considerable edema and mass effect, and on brain MRI they typically enhance on T1-weighted images after the administration of intravenous contrast. Tumor cells have been found in peritumoral edema, which corresponds to T2-weighted signal abnormalities. Thus, this volume is frequently used to define RT treatment volumes.

It can be challenging to assess the results of therapy by brain MRI, because the extent and distribution of contrast enhancement, edema, and mass effect are a function of BBB integrity. Thus, factors that increase permeability of the BBB (such as surgery, RT, tapering of corticosteroids, and immunotherapies) can mimic tumor progression radiographically by increasing the presence of contrast enhancement and associated vasogenic edema. Furthermore, anti-VEGF therapy (ie, bevacizumab) suppresses vascular permeability and provides a radiographic appearance of a response, despite residual disease (pseudoresponse).¹⁴⁵

WHO grade 3 oligodendrogliomas (*IDH*-mutant, 1p19q codeleted) are relatively rare.⁷⁴ This distinct subtype has a much better prognosis compared to other high-grade gliomas (WHO grade 3 *IDH*-mutant astrocytomas and glioblastomas).

Treatment Overview

Surgery

The goals of surgery are to obtain a diagnosis, alleviate symptoms related to increased intracranial pressure or compression by tumor, increase survival, and decrease the need for corticosteroids. A meta-analysis including six studies with 1618 patients with glioblastoma showed that GTR is associated with superior OS and PFS, compared to incomplete resection and biopsy.¹⁴⁶ Unfortunately, the infiltrative nature of high-grade astrocytomas frequently renders GTR difficult. There are data suggesting that resection of all fluid-attenuated inversion recovery (FLAIR) signal abnormalities in high-grade *IDH*-mutant gliomas is associated with improved survival.¹⁴⁷ However, a newer and larger study did not find greater benefit of resection in *IDH*-mutant tumors compared to *IDH* wild-type high-grade gliomas.¹⁴⁸

Unfortunately, nearly all high-grade gliomas recur. Re-resection at the time of recurrence may improve the outcome for select patients.¹⁴⁹ According to an analysis by Park et al,¹⁵⁰ tumor involvement in specific critical brain areas, poor KPS score, and large tumor volume (≥ 50 cm³) were associated with unfavorable re-resection outcomes.

Radiation Therapy

Conformal RT (CRT) techniques, which include 3D-CRT and IMRT, are recommended for performing focal brain irradiation. IMRT often will provide superior dosimetric target coverage and better sparing of critical structures than 3D-CRT.¹²⁵ Several randomized controlled trials conducted in the 1970s showed that radiation improved both local control and survival in patients with newly diagnosed high-grade gliomas.^{151,152}

Sufficient radiation doses are required to maximize this survival benefit. However, radiation dose escalation above 60 Gy has not been shown to be beneficial.¹⁵³ The recommended radiation dose for high-grade astrocytomas is 60 Gy in 2.0 Gy fractions or 59.4 Gy in 1.8 Gy fractions

with an initial RT plan to 46 Gy in 2 Gy fractions or 45 to 50.4 Gy in 1.8 Gy fractions, respectively, followed by a boost plan of 14 Gy in 2 Gy fractions or 9 to 14.4 Gy in 1.8 Gy fractions, respectively.¹⁵³

WHO grade 3 oligodendrogliomas are conventionally treated with the same dose of radiation as WHO grade 3 and 4 *IDH*-mutant astrocytomas and glioblastoma; however, given the better prognosis in patients with oligodendroglioma, radiation treatments are generally administered in a lower dose per fraction (1.8 Gy/fraction vs. 2.0 Gy/fraction) to theoretically decrease the risk of late side effects. Accordingly, as per trials such as RTOG 9813,⁶⁸ these gliomas are treated to 50.4 Gy in 1.8 Gy fractions for 28 fractions followed by a five-fraction boost of 1.8 Gy/fraction to a total of 59.4 Gy. Recurrence of glioma can be managed with reirradiation in select scenarios when clinical trial options and systemic therapy options are limited. This can be performed with either highly focused SRS technique for lower volume disease¹⁵⁴ or fractionated IMRT including doses of 35 Gy in 10 fractions.¹⁵⁵

RT targets for high-grade gliomas are generated from a gross tumor volume (GTV), CTV, and planning target volume (PTV). The GTV encompasses any gross tumor remaining after maximal safe resection as well as the surgical cavity as determined by postoperative imaging. Strategies for GTV definition vary with respect to the inclusion of edema in an initial target volume. When edema is included in an initial phase of treatment, fields are usually reduced for the last phase of treatment. The CTV is an expansion of the GTV by adding an approximately 2-cm margin for WHO grade 3 and 4 gliomas (although smaller CTV expansions are supported in the literature and can be appropriate) to account for a non-enhancing tumor. The CTV is then expanded to a PTV to account for daily setup errors and image registration. The boost target volume will typically encompass only the gross residual tumor and the resection cavity.

Special attention has been given to determining the optimal therapy in older adults with glioblastoma, given their especially poor prognosis, often limited functional status, and increased risk of developing side effects. Overall, the approach in these patients has been to reduce treatment time while maintaining treatment efficacy. Roa et al randomized patients ≥ 60 years with a poor PS (KPS < 70) to 60 Gy in 30 fractions given over 6 weeks versus 40 Gy in 15 fractions given over 3 weeks and found no difference in survival between these two regimens.¹⁵⁶ However, fewer patients who received 40 Gy over a shorter time period required a post-treatment increase in corticosteroid dose, compared to the patients who received 60 Gy over the longer time period (23% vs. 49%, respectively; $P = .02$). A subsequent study provided support for using a regimen of 34 Gy in 10 fractions over 2 weeks in older adult patients.⁵⁴ Moreover, another study performed by Roa et al showed that an even shorter course of focal brain radiation consisting of 25 Gy in 5 fractions over 1 week is a reasonable alternative to 40 Gy in 15 fractions over 3 weeks in patients with newly diagnosed glioblastoma who have a poor prognosis (ie, patients who are older adults and/or frail).¹⁵⁷ However, this was a small study that had some limitations, notably overly broad eligibility criteria and poorly defined non-inferiority margin.^{158,159}

A randomized trial of hypofractionated RT (40 Gy given over 3 weeks) with concurrent and adjuvant TMZ versus hypofractionated RT alone in patients ≥ 65 years showed an improvement in median OS and PFS with the addition of concurrent and adjuvant TMZ (5-year OS of 9.8% vs. 1.9%, respectively; median OS of 14.6 months vs. 12.1 months, respectively; HR for mortality, 0.63; 95% CI, 0.53–0.75; $P < .001$; 5-year PFS of 4.1% vs. 1.3%, respectively; HR, 0.56; 95% CI, 0.47–0.66; $P < .001$).¹⁶⁰ The largest benefit was noted in patients with MGMT promoter methylation (see discussion of *Systemic Therapy for Glioblastoma*, below). Of note, a comparison of standard focal brain radiation (60 Gy given over 6 weeks) with concurrent and adjuvant TMZ versus hypofractionated radiation (40

Gy given over 3 weeks) with concurrent and adjuvant TMZ in elderly patients has not been performed in patients ≥ 65 years. Therefore, standard radiation (60 Gy given over 6 weeks) with concurrent and adjuvant TMZ (with or without alternating electric field therapy; see discussion of this treatment option below) is also a reasonable treatment option for an older adult patient who has a good PS and wishes to be treated aggressively. Ultimately, quality of life remains an important consideration in the optimal management of this patient population.

Systemic Therapy

WHO Grade 3 Oligodendroglioma (IDH-mutant, 1p19q codeleted)

The addition of PCV to RT for the treatment of newly diagnosed WHO grade 3 oligodendrogliomas is supported by results from two phase III trials, one which tested RT followed by PCV for 6 cycles (EORTC 26951^{161,162}) and the other which assessed 4 cycles of dose-intensive PCV administered prior to RT (RTOG 9402^{44,163,164}). Both studies compared the combination therapy to RT alone and found significant increases in median OS when PCV was added to RT for the upfront management of WHO grade 3 oligodendroglioma.

The EORTC 26951 trial showed that, among the entire group of 368 histopathologically diagnosed study patients with anaplastic oligodendroglioma or anaplastic oligoastrocytoma (based on the 1993 WHO classification¹⁶⁵), RT followed by 6 cycles of PCV significantly improved median PFS and OS (42.3 vs. 30.6 months; HR, 0.75; 95% CI, 0.60–0.95; $P = .018$) compared with RT alone.¹⁶² Moreover, in an exploratory subgroup analysis of the 80 patients whose tumors were 1p19q codeleted (grade 3 oligodendroglioma based on the 2021 WHO classification), the benefit was even more pronounced (OS not reached in the RT + PCV group vs. 112 months in the RT group; HR, 0.56; 95% CI, 0.31–1.03).^{20,161,162}

RTOG 9402 randomized 291 patients with histopathologically diagnosed anaplastic oligodendroglioma or anaplastic oligoastrocytoma to treatment with an intensive PCV regimen followed by RT or RT alone.¹⁶⁴ As with EORTC 26951, the inclusion of patients with “anaplastic” glioma was based on an earlier WHO classification.⁵ In contrast to the EORTC 26951 study, no difference in median OS was observed between the two arms (4.6 years vs. 4.7 years; HR, 0.79; 95% CI, 0.60–1.04; $P = .10$). However, an unplanned subgroup analysis of the 126 patients whose tumors were 1p19q codeleted found a doubling in median OS (14.7 vs. 7.3 years; HR, 0.59; 95% CI, 0.37–0.95; $P = .03$) when PCV was added to RT as upfront treatment.

As would be predicted, in both studies toxicity was higher in the treatment arms that included PCV. In EORTC 26951, 70% of patients in the RT followed by PCV arm did not complete the planned six cycles of treatment.^{161,162} In RTOG 9402, there was also a high rate of study treatment discontinuation and acute toxicities (mainly hematologic), including two early deaths attributed to PCV-induced neutropenia.^{163,164} Given the similar efficacy results of the two studies, and the two deaths that occurred from the intensive PCV regimen in RTOG 9402, the panel recommends that PCV be administered after RT, as per EORTC 26951, for optimal management.

The phase III CODEL study was designed to assess the efficacy of TMZ for the treatment of newly diagnosed WHO grade 3 oligodendrogliomas. The initial treatment arms were RT alone, RT + TMZ, and TMZ alone. Initial results showed that patients who received TMZ alone had significantly shorter PFS than patients treated with RT (either RT alone or with TMZ) (2.9 years vs. not reached, respectively; HR, 3.12; 95% CI, 1.26–7.69; $P = .009$).¹⁶⁶ When the results of RTOG 9402 and EORTC 26951 were reported showing significant improvement in median OS with RT + PCV upfront in patients with WHO grade 2 oligodendroglioma, the

CODEL study was redesigned to compare RT + PCV to RT + TMZ in patients with WHO grade 2 or 3 oligodendroglioma. This study is ongoing.

WHO Grade 3 and 4 IDH-Mutant Astrocytoma

The RTOG 9813 trial showed that RT with concurrent TMZ resulted in similar outcomes as RT with concurrent nitrosourea (either CCNU [lomustine] or BCNU [carmustine]) therapy in patients with newly diagnosed anaplastic (grade 3) astrocytomas. At the time of study accrual, the diagnosis of anaplastic (grade 3) astrocytoma was based on tumor morphology. Retrospective analysis of tumor tissue showed that 44.1% of study participants had tumors that were *IDH1-R132H* mutated. There was perhaps slightly better PFS with TMZ (HR, 0.70; 95% CI, 0.50–0.98; $P = .039$),⁶⁸ however, the toxicity of nitrosourea was significantly worse than for TMZ, and resulted in higher rates of discontinuation due to toxicity (79% vs. 40%, respectively; $P < .001$).

The ongoing CATNON phase 3 randomized trial is testing RT alone, as well as RT with adjuvant TMZ, concurrent TMZ, or both, in patients with newly diagnosed anaplastic astrocytoma. As in previous trials,^{161,163} the inclusion of patients with “anaplastic astrocytoma” is based on an earlier WHO classification.⁵ An initial interim analysis showed that adjuvant TMZ significantly improved PFS (HR, 0.62; 95% CI, 0.50–0.76) and OS (HR, 0.67; 95% CI, 0.51–0.88).¹⁴⁰ Median OS for the group of patients treated with post-RT TMZ had not been reached, but median OS at 5 years was 55.9% (95% CI, 47.2–63.8) with and 44.1% (36.3–51.6) without adjuvant TMZ. A second interim analysis showed that, in terms of OS, patients with *IDH*-mutant anaplastic astrocytomas (grade 3 *IDH*-mutant astrocytoma, per the WHO 2021 classification) benefitted from treatment with adjuvant TMZ (HR, 0.48; 95% CI, 0.35–0.67; $P < .0001$), but not those participants whose tumors were *IDH* wild-type (HR, 1.00; 95% CI, 0.75–.98; $P = 0.98$).¹⁶⁷ There was also no definite benefit to concurrent TMZ in patients

with *IDH*-mutant anaplastic astrocytomas (HR, 0.80; 95% CI, 0.58–1.10; $P = .17$). Further follow-up and molecular analyses are ongoing.

Glioblastoma

Adjuvant involved-field RT with concurrent and adjuvant TMZ is the standard recommended treatment for patients with newly diagnosed glioblastoma and good PS based on the results of the phase III, randomized EORTC-NCIC study of 573 patients with newly diagnosed glioblastoma who were aged ≤ 70 years and had a WHO PS ≤ 2 .¹⁶⁰ Patients received either 1) daily TMZ administered concomitantly with postoperative RT followed by 6 cycles of adjuvant TMZ; or 2) RT alone. The chemoradiation arm resulted in a statistically better median survival (14.6 vs. 12.1 months) and 2-year survival (26.5% vs. 10.4%) when compared with RT alone. Final analysis confirmed the survival advantage at 5 years (10% vs. 2%).¹⁶⁰ However, the study design does not shed light on which component is responsible for the improvement: TMZ administered with RT, TMZ following RT, or possibly both.

The TMZ dose used in the EORTC-NCIC trial is 75 mg/m² daily concurrent with RT, then 150 to 200 mg/m² post-irradiation on a 5-day schedule every 28 days. Alternate schedules, such as a 75 to 100 mg/m² for 21 out of 28 days regimen or 50 mg/m² daily, have been explored in a phase II trial for newly diagnosed glioblastoma.¹⁶⁸ However, a comparison of the dose-intense 21/28 and standard 5/28 schedules in the RTOG 0525 phase III study showed no difference in PFS, OS, or by MGMT methylation status with the post-radiation dose-intense TMZ, compared to the standard post-radiation TMZ dose.¹⁶⁹ A pooled analysis of individual patient data from four randomized trials^{142,169-171} of patients with newly diagnosed glioblastoma determined that treating with post-radiation TMZ beyond six cycles does not improve OS, even for patients whose tumors are MGMT promoter methylated.¹⁷² A recent prospective, randomized phase II study showed no improvement in 6-month PFS, PFS, or OS with continuing

treatment with TMZ beyond 6 cycles, and doing so was associated with greater toxicity.¹⁷³

MGMT Promoter-Methylated Glioblastoma

The presence of MGMT promoter methylation in glioblastoma is both a prognostic marker and a predictive one for response to treatment with alkylating agents. In the small (N = 31), single-arm phase II UKT-03 trial,^{174,175} postoperative RT and TMZ combined with lomustine in patients with newly diagnosed glioblastoma resulted in a median OS of 34.3 months,¹⁷⁴ which compared favorably to the historical control data of 23.4 months in patients with MGMT promoter-methylated tumors who were treated with RT and TMZ in the EORTC-NCIC trial.¹⁶⁰ Based on this improvement in survival with combination alkylating agents in patients with MGMT promoter-methylated glioblastoma, the phase III CeTeG/NOA-09 trial randomized patients with newly diagnosed MGMT-promoter-methylated glioblastoma (aged 18–70 and KPS ≥70) to treatment with RT and lomustine + TMZ or RT and TMZ alone.¹⁷⁶ Analysis of the modified intent-to-treat population (N = 129) showed that OS was significantly improved in the TMZ + lomustine arm versus the TMZ arm (median OS of 48.1 months vs. 31.4 months, respectively; $P = .049$). Of note, PFS was not significantly improved, which the investigators hypothesized could have been due to a higher incidence of pseudoprogression in the TMZ + lomustine arm. Grade 3 and 4 adverse events were only slightly higher in the TMZ + lomustine arm (59% vs. 51%, respectively), but the study was too small to adequately define the toxicity profile of RT with TMZ + lomustine. Analysis of health-related quality of life showed no significant differences between the study arms.¹⁷⁷

Older Adults

Building on the findings that hypofractionated RT alone has similar efficacy and is better tolerated compared to standard RT alone in older adults with newly diagnosed glioblastoma, a phase III randomized trial with 562 newly

diagnosed patients ≥65 years of age compared hypofractionated RT with concurrent and adjuvant TMZ to hypofractionated radiation alone. Patients in the combination therapy arm had better PFS (5.3 months vs. 3.9 months; HR, 0.50; 95% CI, 0.41–0.60; $P < .001$) and median OS (9.3 months vs. 7.6 months; HR, 0.67; 95% CI, 0.56–0.80; $P < .001$) compared to patients treated with hypofractionated RT alone.¹⁴¹ The greatest improvement in median OS was seen in patients with MGMT promoter-methylated tumors (13.5 months RT + TMZ vs. 7.7 months RT alone; HR, 0.53; 95% CI, 0.38–0.73; $P < .001$). The benefit of adding TMZ to RT was smaller in patients with MGMT promoter-unmethylated tumors and did not quite reach statistical significance (10.0 months vs. 7.9 months, respectively; HR, 0.75; 95% CI, 0.56–1.01; $P = .055$; $P = .08$ for interaction).

Two phase III studies in elderly newly diagnosed glioblastoma patients assessed treatment with TMZ alone versus radiation.^{54,55} The Nordic trial randomized 291 patients aged ≥60 years with good PS across three treatment groups: TMZ, hypofractionated RT, or standard RT.⁵⁴ Patients >70 years had better survival with TMZ or hypofractionated RT compared to standard RT, and patients whose tumors were MGMT promoter-methylated benefitted more from treatment with TMZ compared to patients with MGMT promoter-unmethylated tumors (median OS 9.7 vs. 6.8 months; HR, 0.56; 95% CI, 0.34–0.93; $P = .02$). The NOA-08 study assessed the efficacy of TMZ alone compared to standard RT in 373 patients aged ≥65 years.⁵⁵ TMZ was found to be noninferior to standard RT; median OS was similar in both groups (8.6 months in the TMZ arm vs. 9.6 months in the standard RT arm; HR, 1.09; 95% CI, 0.84–1.42; P [non-inferiority] = .033). For patients whose tumors were MGMT promoter-methylated, event-free survival was longer with TMZ treatment compared to standard RT (8.4 months vs. 4.6 months). Neither the Nordic trial nor the NOA-08 trial included a combination RT and TMZ control arm, which is the treatment regimen typically offered to patients who are fit enough to

tolerate it, regardless of age. Although radiation in combination with TMZ is recommended over single-modality therapy for newly diagnosed patients with glioblastoma who are >70 years of age and have good PS, the results of these two phase III studies support the recommendation that TMZ alone as initial therapy may be a reasonable option for those elderly patients who have MGMT promoter-methylated tumors and would initially prefer to delay treatment with radiation.^{54,55}

Alternating Electric Field Therapy

In 2015, the FDA approved alternating electric field therapy for the treatment of patients with newly diagnosed glioblastoma based on the results of the open-label phase III EF-14 clinical trial. This portable medical device generates low-intensity alternating electric fields to stop mitosis/cell division. In the EF-14 trial, 695 patients with newly diagnosed glioblastoma and good PS (KPS ≥70) were randomized to TMZ alone on a 5/28-day schedule or the same TMZ and alternating electric field therapy, following completion of standard focal brain radiation and daily TMZ.¹⁷⁸ The results of the study showed an improvement in median PFS (6.7 vs. 4.0 months, respectively; HR, 0.63; 95% CI, 0.52–0.76; $P < .001$) and OS (20.9 vs. 16.0 months, respectively; HR, 0.63; 95% CI, 0.53–0.76; $P < .001$) in patients who received TMZ plus alternating electric field therapy.¹⁷⁹ The number of adverse events was not statistically different between the two treatment groups except for a greater frequency of mild to moderate local skin irritation/itchiness in the patients treated with the alternating electric fields.¹⁸⁰ There was no increased frequency of seizures.^{181,182} Based on the results of this study, concurrent treatment with adjuvant TMZ and alternating electric fields is a category 1 recommendation for newly diagnosed glioblastoma patients ≤70 years of age who have a good PS. This is also considered a reasonable treatment option for patients >70 years of age with good PS and newly diagnosed glioblastoma who are treated with standard focal brain radiation and concurrent daily TMZ.

Therapy for Recurrence

Patients with malignant gliomas eventually develop tumor recurrence or progression. Surgical resection of locally recurrent disease is reasonable followed by treatment with systemic therapy. Unfortunately, there is no established second-line therapy for recurrent gliomas. If there has been a long-time interval between stopping TMZ and development of tumor progression, it is reasonable to restart a patient on TMZ,¹⁸³ particularly if the patient's tumor is MGMT methylated. Similarly, a nitrosourea, such as carmustine or lomustine,¹⁸⁴⁻¹⁸⁷ would be a reasonable second-line therapy, especially in a patient whose tumor is MGMT methylated. Although no studies of bevacizumab in patients with recurrent glioblastoma have demonstrated an improvement in survival, bevacizumab is FDA approved for the treatment of recurrent glioblastoma based on improvement in PFS.¹⁸⁸⁻¹⁹⁰ Of note, improvement in PFS may be due to bevacizumab's ability to decrease BBB permeability (resulting in less contrast enhancement and vasogenic edema) rather than a true anti-tumor effect.^{191,192} Treatment with regorafenib for recurrent glioblastoma is supported by the results of a randomized phase II trial in which OS was greater for patients randomized to receive regorafenib, compared to those who received lomustine (median OS of 7.4 months vs. 5.6 months, respectively; HR, 0.50; 95% CI, 0.33–0.75; $P < .001$).¹⁹³ Of note, the median OS in the lomustine arm in this trial was lower than reported in other randomized phase II and III trials. A phase III study of regorafenib is being planned.

Other routes of chemotherapy delivery have been evaluated. Local administration of carmustine using a biodegradable polymer (wafer) placed intraoperatively in the surgical cavity has demonstrated a statistically significant improvement in survival for patients with recurrent high-grade gliomas (31 vs. 23 weeks; adjusted HR, 0.67; $P = .006$).¹⁹⁴ Patients who receive carmustine wafers are at greater risk for seizures and postoperative infections. When wafers are used, it is important to

achieve a watertight dural closure and have sufficient use of steroids and antiepileptics in the perioperative period to prevent adverse events.¹⁹⁵ Clinicians and patients should be aware that treatment with the carmustine wafer may prevent participation in a clinical trial involving a locally delivered investigational agent.

Alternating electric field therapy is also FDA approved for treating recurrent glioblastoma based on the safety results of this medical device from the EF-11 clinical trial.¹⁹⁶ This phase III study randomized 237 patients with recurrent glioblastoma to alternating electric field therapy or the treating oncologist's choice of chemotherapy. The study did not meet its primary endpoint of demonstrating an improvement in survival in the cohort of patients treated with alternating electric field therapy. Although median OS was similar in both of the treatment arms (6.6 vs. 6 months), the study had not been powered for a non-inferiority determination. Due to lack of clear efficacy data for alternating electric field therapy in EF-11, the panel is divided about recommending it for the treatment of recurrent glioblastoma. Similarly, re-irradiation may be reasonable to consider for some recurrent glioblastoma patients, but the panel is also divided about this option. A systematic review including 50 non-comparative studies of 2095 patients with recurrent glioblastoma who were treated with re-irradiation showed pooled 6- and 12-month OS rates of 73% and 36%, respectively, and 6- and 12-month PFS rates of 43% and 17%, respectively.¹⁹⁷ Over half of the studies (29 out of 50) were rated as poor quality, indicating a need for better quality studies in this area. Further, there is no recommended dose or type of radiation used in the recurrent setting due to inconsistent trial design among these studies.

NCCN Recommendations

Primary Treatment

When a patient presents with a clinical and radiologic picture suggestive of a high-grade glioma, neurosurgical input is needed regarding the feasibility

of maximal safe resection. For first-line treatment of high-grade glioma, the NCCN Guidelines recommend maximal safe resection whenever possible. One exception is when CNS lymphoma is suspected; a biopsy should be performed before steroids are administered, and management should follow the corresponding pathway if the diagnosis is confirmed. When maximal resection is performed, the extent of tumor debulking should be documented with a postoperative MRI scan with and without contrast performed within 48 hours after surgery. Multidisciplinary consultation is encouraged once the pathology is available.

Adjuvant Therapy

RT is generally recommended after maximal safe resection for the treatment of high-grade gliomas to improve local control and survival. For postoperative treatment of WHO grade 3 oligodendroglioma (*IDH*-mutant, 1p19q codeletion) and WHO grade 3 or 4 *IDH*-mutant astrocytoma in patients with good PS (KPS ≥ 60), focal brain radiation and chemotherapy are the recommended options. For patients with WHO grade 3 oligodendroglioma, RT plus PCV, given before or after RT, is preferred, based on the results of the RTOG 9402^{44,164} and EORTC 26951 studies.^{161,162} The panel advises administering PCV after RT as per EORTC 26951 instead of the dose-intensive PCV used prior to RT in the RTOG 9402 study¹⁶⁴ due to better patient tolerance. Regarding PCV, carmustine may be substituted for lomustine. RT, with or without concurrent TMZ, followed by adjuvant TMZ is also a reasonable option,¹⁹⁸ particularly if it is predicted that the patient might have significant difficulty tolerating PCV due to age or coexisting medical conditions. The panel awaits the results of the CODEL study to see if treatment with TMZ will be as efficacious as PCV in this patient population.

In the case of patients with WHO grade 3 or 4 *IDH*-mutant astrocytoma and good PS, RT, with or without concurrent TMZ and followed by adjuvant TMZ, is preferred based on the second interim analysis results of

the CATNON trial showing improvement in survival with RT followed by 12 cycles of TMZ compared to RT alone.^{140,167}

For patients diagnosed with glioblastoma, the adjuvant options mainly depend on the patient's age, PS (as defined by KPS), and MGMT promoter methylation status.^{51,54,160,199} Category 1 recommendations for patients aged ≤ 70 years with a good PS, regardless of the tumor's MGMT methylation status, include standard brain RT plus concurrent and adjuvant TMZ with or without alternating electric field therapy. Because patients with newly diagnosed MGMT promoter-unmethylated glioblastoma are likely to receive less benefit from TMZ, RT alone is included as a reasonable option, particularly if the patient is eligible to participate in a clinical trial, which omits the use of upfront TMZ.

Category 1 treatment recommendations for patients >70 years of age with newly diagnosed glioblastoma, a good PS, and MGMT promoter-methylated tumors include hypofractionated brain RT plus concurrent and adjuvant TMZ¹⁴¹ or standard brain RT plus concurrent and adjuvant TMZ and alternating electric field therapy. For those patients >70 years with newly diagnosed glioblastoma, a good PS, and with MGMT-unmethylated or -indeterminant tumors, hypofractionated brain radiation with concurrent and adjuvant TMZ¹⁴¹ is preferred, but standard brain RT plus concurrent and adjuvant TMZ and alternating electric field therapy is also a reasonable option (category 1)^{178,179} for patients >70 years of age who want to be treated as aggressively as possible. The complete list of recommendations that the panel did not consider category 1 can be found in the treatment algorithms for patients with glioblastoma who are >70 years.

For patients with poor PS (KPS <60) who have newly diagnosed WHO grade 3 oligodendroglioma (*IDH*-mutant, 1p19q codeletion) or WHO grade 3 or 4 *IDH*-mutant astrocytoma, hypofractionated brain RT with or without concurrent or adjuvant TMZ is preferred. For patients with glioblastoma

who have a poor PS (regardless of age), single modality therapy is recommended: hypofractionated brain RT or TMZ for patients with MGMT promoter-methylated tumors. Palliative/best supportive care is also a reasonable option for patients with newly diagnosed high-grade gliomas with poor PS.

Follow-up and Recurrence

Patients should be followed closely with serial brain MRI scans (at 2–8 weeks post-irradiation, then every 2–4 months for 3 years, then every 3–6 months indefinitely) after the completion of treatment for newly diagnosed disease. Scans may appear worse during the first 3 months or longer after completion of RT even though there may be no actual tumor progression.¹⁴⁴ This finding of “pseudoprogression” occurs more often in patients whose tumors are MGMT promoter methylated.^{200,201} Early MRI scans allow for appropriate titration of corticosteroid doses based on the extent of mass effect and brain edema. Later scans are used to identify tumor recurrence. Early detection of recurrence is warranted, because local and systemic treatment options are available for patients with recurrent disease. Biopsy, MR spectroscopy, MR perfusion, or brain PET/CT can be considered to try to determine if the changes seen on brain MRI are due to pseudoprogression or RT-induced necrosis versus actual disease progression.^{202,203} RT-induced necrosis tends to be detected between 6 and 24 months following RT treatment.²⁰¹

Management of recurrent tumors depends on the extent of disease and patient condition. The efficacy of current treatment options for recurrent disease remains poor; therefore, enrollment in a clinical trial, whenever possible, is preferred for the management of recurrent disease. Preferred systemic therapy options for recurrent disease include re-treatment with TMZ (if there has been a long interval between completion of adjuvant TMZ and development of recurrent disease),^{133,183,204-206} carmustine/lomustine,^{184-187,207} bevacizumab,^{188,208-213} regorafenib,¹⁹³ and

PCV.^{134,214,215} A patient with a poor PS should receive palliative/best supportive care.

Intracranial and Spinal Ependymomas

Ependymomas constitute up to 1.6% of CNS tumors.⁷⁴ In adults, ependymomas occur more often in the spinal canal than in the intracranial compartment (supratentorial and posterior fossa). These tumors can cause hydrocephalus and increased intracranial pressure, mimic brainstem lesions, cause multiple cranial nerve palsies, produce localizing cerebellar deficits, and cause neck stiffness and head tilt if they infiltrate the upper portion of the cervical cord.^{216,217} Posterior fossa ependymomas are categorized as two groups: A (PFA) and B (PFB). PFA ependymomas are more common in infants and young children, and typically behave in a more aggressive manner than PFB ependymomas.

This section focuses on adult spinal and intracranial ependymal tumors, including grade 2 differentiated (classic ependymomas) and grade 3 (anaplastic ependymomas) tumors. The NCCN Guidelines also include recommendations for management of myxopapillary spinal ependymomas. cIMPACT-NOW recommends diagnosing myxopapillary ependymomas as grade 2,²¹⁸ as outcomes for these tumors are not significantly different than those for classic ependymoma.²¹⁹

Molecular Markers

Ependymomas arising in the supratentorium often contain activating fusions of *ZFTA*, with the most common *ZFTA* partner being *RELA*. *RELA* activating fusions occur in about 19% of patients with ependymomas and are more likely to occur in children than in adults.²²⁰ Ependymomas with *RELA* activating fusions are more likely to be advanced and aggressive than *RELA* fusion-negative ependymomas (including those with *YAP1* fusion), with a greater likelihood of being grade 2 or 3, and with shorter PFS and OS.^{220,221} In the 2016 WHO classification system, *RELA* fusion-

positive ependymoma was designated as a subtype.⁵ Testing for *ZFTA* and *YAP1* fusions is recommended when clinically appropriate.

MYCN-amplified spinal ependymoma has been identified as an aggressive form of ependymoma^{222,223} and thus is now designated as a subtype in the 2021 WHO classification.^{6,218} Loss of H3K27 trimethylation by IHC is characteristic of PFA ependymomas, and genomic methylation profiling is recommended for differentiation of PFA and PFB ependymomas.^{24,218,224}

Treatment Overview

Surgery

There is a paucity of robust studies addressing the role of surgery in this uncommon disease, but multiple case series have reported that patients with totally resected tumors tend to have the best survival for both low- and high-grade ependymomas.²²⁵⁻²²⁹ Grade 1 subependymomas are non-infiltrative and can often be cured by resection alone. For myxopapillary ependymomas, complete resection of the mass without capsular violation (marginal en bloc resection) can be curative.²³⁰ In a retrospective analysis by Rodriguez et al,²³¹ patients who underwent surgery had a better outcome than those who did not (HR, 1.99; $P < .001$). Supratentorial ependymomas generally have a poorer prognosis than their infratentorial counterparts, because a greater proportion of supratentorial lesions are of high grade.

Radiation Therapy

The survival benefits of RT following surgery have been established for anaplastic ependymomas and suboptimally resected tumors, although much of the data are derived from pediatric patients. Rodriguez et al²³¹ reviewed over 2400 cases of ependymomas in the SEER database and reported that patients with partially resected tumors who do not receive RT have a poorer prognosis than those who are treated with RT (HR, 1.75; $P = .024$). The short-term and 10-year survival rate after RT reached over

70% and 50%, respectively.²³²⁻²³⁴ The value of RT is more controversial for differentiated ependymomas,^{226,235} with data demonstrating improved survival mainly for subtotally resected tumors.^{227,231} Emerging data show poor survival rates in patients with supratentorial non-anaplastic ependymoma who do not receive RT following GTR.²³⁶ Further, much of the data supporting observation following surgical resection are based on retrospective studies.²³⁷⁻²³⁹ Given the availability of highly CRT modalities and the relatively lower level of concerns for late effects of RT in adults (vs. children), RT is recommended as the standard adjuvant treatment approach in these patients until high-quality evidence supporting observation alone becomes available.

In the past, the standard practice was to irradiate the entire craniospinal axis or administer WBRT. However, studies have demonstrated that: 1) local recurrence is the primary pattern of failure; 2) spinal seeding is uncommon in the absence of local failure; 3) the patterns of failure are similar in patients with high-grade tumors who are treated with local fields or craniospinal axis irradiation; and 4) spinal metastases may not be prevented by prophylactic treatment.²⁴⁰⁻²⁴² Prophylactic craniospinal RT or WBRT does not lead to improvement in survival compared to conformal regional RT with higher doses in modern studies of non-disseminated disease.^{228,235,243}

The typical craniospinal irradiation scheme includes 36 Gy in 1.8 Gy fractions to the whole brain and spine, followed by limited-field irradiation to spine lesions to 45 Gy. For intracranial ependymomas, the primary brain site should receive a total of 54 to 59.4 Gy in 1.8 to 2.0 Gy fractions. PTV of margin of 3 to 5 mm is typically added to the CTV. Tolerance of the cauda equina is in the range of 54 to 60 Gy.^{244,245} Therefore, a boost to gross intracranial metastatic sites (respecting normal tissue tolerances) may be considered.

For spinal ependymomas, patients could receive local RT to 45 to 54 Gy in 1.8 Gy fractions, with higher doses up to 60 Gy being reasonable for spinal tumors below the conus medullaris. These dosing recommendations are consistent with those for primary spinal cord tumors. However, it is important to note that retrospective analyses have shown that adjuvant RT does not consistently improve disease outcomes in patients with these tumors.²⁴⁶⁻²⁴⁸

Proton beam craniospinal irradiation may be considered when clinically appropriate and when toxicity is a concern. SRS has been used as a boost after EBRT or to treat recurrence with some success, although data on long-term results are still lacking.²⁴⁹⁻²⁵¹

Systemic Therapy

Studies regarding the role of chemotherapy have largely been in the setting of pediatric ependymomas; the role of chemotherapy in the treatment of ependymomas in adult patients remains poorly defined. No study has demonstrated a survival advantage with the addition of chemotherapy to RT in newly diagnosed tumors. However, chemotherapy is sometimes considered as an alternative to palliative/best supportive care or RT in the recurrence setting. Possible options include platinum-based regimens (cisplatin or carboplatin),^{252,253} etoposide,^{254,255} nitrosourea-based regimens (lomustine or carmustine),²⁵³ bevacizumab,²⁵⁶ and temozolomide.²⁵⁷ The combination of lapatinib, a tyrosine kinase inhibitor (TKI), and dose-dense TMZ has been evaluated in a phase II trial in patients with recurrent grade 1, 2, and 3 ependymoma.²⁵⁸

NCCN Recommendations

Primary and Adjuvant Treatment

In general, when feasible, management of rare tumors such as ependymomas should begin with a timely and early consultation with centers of neuro-oncologic expertise. Whenever possible, maximal safe

resection should be attempted with contrast-enhanced brain image verification within 48 hours after surgery. Spine MRI, if not done prior to surgery, should be delayed by at least 2 to 3 weeks after surgery to avoid post-surgical artifacts. If maximal resection is not feasible at diagnosis, STR or biopsy (stereotactic or open) should be performed. Due to the established relationship between the extent of resection and outcome, multidisciplinary review and re-resection (if possible) should be considered if MRI shows that initial resection is incomplete. For spinal myxopapillary ependymomas, en bloc resection without capsule violation is recommended whenever feasible.

The adjuvant treatment algorithm depends on the extent of surgical resection, histology, and staging by craniospinal MRI and cerebrospinal fluid (CSF) cytology. For spinal ependymomas, brain MRI should be obtained to determine if these are drop metastases from a primary brain lesion. CSF dissemination develops in up to 15% of intracranial ependymomas. Lumbar puncture for CSF cytology, which is indicated when there is clinical concern for meningeal dissemination, should be done following spine MRI and, if not done prior to surgery, should be delayed at least 2 weeks after surgery to avoid a false-positive result. Lumbar puncture may be contraindicated in some cases (for example, if there is increased intracranial pressure and risk of herniation).

RT is the appropriate postoperative management for patients with negative findings for tumor dissemination on MRI scans and CSF analysis. Patients with grade 1 spinal ependymomas that have been totally resected may not require adjuvant RT, as the recurrence rate tends to be low. For patients who have undergone maximum safe resection for low-grade intracranial ependymoma with no signs of dissemination on MRI and CSF analysis, adjuvant RT may be considered. RT is also an adjuvant treatment option for patients with myxopapillary ependymoma who had an STR or if capsule violation occurred, even if CSF cytology is negative.

Craniospinal RT is recommended when MRI spine or CSF results reveal metastatic disease, regardless of histology and extent of resection.

Follow-up and Recurrence

Follow-up of ependymoma depends on tumor grade and the location and extent of the disease. For localized disease, contrast-enhanced brain and spine MRI (if initially positive) should be done 2 to 3 weeks postoperatively and then every 3 to 4 months for one year. The interval can then be extended to every 4 to 6 months in the years 2 through 4, every 6 to 12 months for years 5 through 10, then as clinically indicated depending on the physician's concern regarding the extent of disease, histology, and other relevant factors. If tumor recurrence in the brain or spine is noted on one of these scans, restaging by brain and spine MRI as well as CSF analysis is necessary. More frequent MRI scans may also be indicated indefinitely for close follow-up in this setting. Resection is recommended if possible.

Upon disease progression or recurrence, treatment options depend on extent of disease, imaging and CSF findings, and prior treatment. For patients not previously irradiated, treatment with RT or consideration of SRS in appropriate cases for localized recurrence (negative MRI scan and CSF results), or craniospinal RT, when there is evidence of neuraxis metastasis, is recommended. For patients who have received prior RT treatment, clinical trials, systemic therapy, or palliative/best supportive care (in the setting of poor functional status) are the treatment options for those with evidence of recurrence with or without metastasis based on imaging and CSF findings. Patients who have received prior RT, are in good functional status, and do not show evidence of neuraxis metastatic disease should be considered for enrollment in a clinical trial. Re-irradiation and systemic therapy may also be considered for these patients, as clinically appropriate.

Adult Medulloblastoma

Although medulloblastoma is the most common brain tumor in children, it also can occur in adults,²⁵⁹ though it makes up only 1% of CNS tumors in adults.²⁶⁰ These tumors are often located in the cerebellar hemisphere²⁶¹ and can be broken into distinct molecular subtypes: WNT-activated, SHH-activated, and non-WNT/non-SHH.^{6,259,262} Subtype analysis continues to evolve.²⁶³ Adult medulloblastoma tends to be different genomically from pediatric medulloblastoma, including differing prognostic markers.²⁶⁴ 6q loss is a prognostic marker in pediatric medulloblastoma, but not in adult medulloblastoma.²⁶⁵ Tumors activated by SHH signaling are common in adult medulloblastoma.^{259,265,266} Metastatic disease is less common in adult medulloblastoma than in children. It tends to occur in patients with non-WNT, non-SHH disease.²⁶⁷ One study showed that tumors activated by WNT signaling are associated with good OS outcomes ($P < .001$), based on a sample of patients with medulloblastoma that included children, infants, and adults, though trends were not statistically significant in analysis including only adults ($n = 65$).²⁵⁹ An analysis of 28 adult patients with medulloblastomas showed that WNT signaling was associated with worse prognosis.²⁶⁵ Somatic *CTNNB1* mutations are very common in WNT-activated tumors; germline *APC* mutations occur in these tumors as well but are less common.²⁶⁸ In patients with tumors activated by SHH signaling, prognosis is poor for those with tumors that are *TP53*-mutant, compared to those with SHH-activated tumors that are not *TP53*-mutant, even when controlling for histology, sex, presence of distantly metastatic disease, and age.²⁶⁹ Therefore, WHO further classifies SHH-mutant medulloblastoma as *TP53*-mutant and *TP53* wild-type.^{6,270}

Treatment Overview

Since adult medulloblastoma is a rare adult CNS malignancy, patients should be considered for referral to specialized brain tumor centers. Given the impact of surgical treatment on survival, need for reproductive endocrine and fertility evaluation, consideration of stem cell collection, and

the role of early neuro-rehabilitation, the panel strongly recommends referral to a specialized brain tumor center with experience in medulloblastoma. Adjuvant treatment initiation should not be delayed. Patients with rare CNS tumors should be considered for registration in national registries of rare tumors, <https://clinicaltrials.gov/ct2/show/NCT02851706>.

Surgery

Evidence in adult patients is meager for this rare disease and there are no randomized trial data, but there is general consensus that surgical resection should be the routine initial treatment to establish diagnosis, relieve symptoms, and maximize local control. Complete resection can be achieved in half of the patients²⁷¹⁻²⁷³ and is associated with improved survival.^{271,274} When viewed by molecular subtype, near-total resection (<1.5 cm residual) and GTR produced equivalent OS for SHH, WNT, and Group 3 patients.²⁷⁵ In addition, surgical placement of a ventriculoperitoneal shunt can be used to treat hydrocephalus.

Radiation Therapy

Adjuvant RT following surgery is the current standard of care, although most studies are based on the pediatric population. The conventional dose is 30 to 36 Gy of craniospinal irradiation and a boost to a total of 54 to 55.8 Gy to the primary brain site.^{271,274} Data from pediatric trials support use of a lower craniospinal dose of 23.4 Gy, combined with systemic therapy, while maintaining 54 to 55.8 Gy to the posterior fossa.²⁷⁶⁻²⁷⁸ A randomized pediatric trial for standard-risk patients treated with radiation alone found an increased relapse risk with dose reduction.²⁷⁹ A multicenter study including 70 adults with nonmetastatic medulloblastoma showed that reduced-dose craniospinal irradiation (23.4 or 35.2 Gy with a boost of 55.2 Gy to the fossa posterior) with maintenance chemotherapy is feasible.²⁸⁰ It is reasonable to consider proton beam for craniospinal irradiation where available, as it is associated with less toxicity.²⁸¹ SRS demonstrated safety

and efficacy in a small series of 12 adult patients with residual or recurrent disease.²⁸² Concomitant chemotherapy (vincristine) is typically omitted in adults given potential for severe toxicity.

Systemic Therapy

The use of post-irradiation systemic therapy to allow RT dose reduction is becoming increasingly common especially for children,^{276,277} but optimal use of adjuvant chemotherapy is still unclear for adult patients.^{273,283-286}

Neoadjuvant therapy has not shown a benefit in pediatric or adult patients.²⁸⁷⁻²⁸⁹ It is used in infants to defer radiation. A phase III study that enrolled more than 400 patients between 3 and 21 years of age with average-risk disease to receive post-irradiation cisplatin-based chemotherapy regimens recorded an encouraging 86% 5-year survival.²⁷⁸

In the setting of recurrence, several regimens are in use in the recurrence setting, most of which include etoposide.²⁹⁰⁻²⁹³ Temozolomide has also been used in this setting.^{133,294} High-dose chemotherapy in combination with autologous stem cell transplantation is a feasible strategy for patients who have had good response with conventional-dose chemotherapy, although long-term control is rarely achieved.^{292,295} SHH-pathway inhibitors that have been evaluated in phase II trials including adults with recurrent medulloblastoma include vismodegib²⁹⁶ and sonidegib.²⁹⁷ Patients in these trials with SHH-activated disease were more likely to respond than patients with non-SHH disease.^{296,297}

NCCN Recommendations

Primary Treatment

MRI scan is the gold standard in the assessment of medulloblastoma. The typical tumor shows enhancement and heterogeneity. Diffusion-weighted abnormalities are also characteristic of medulloblastoma. Fourth ventricular floor infiltration is a common finding related to worse prognosis.^{283,285,286} Multidisciplinary consultation before treatment initiation

is advised. Maximal safe resection is recommended wherever possible. Contrast-enhanced brain MRI should be performed within 48 hours following surgery, but spinal MRI should be delayed by 2 to 3 weeks. Because of the propensity of medulloblastoma to CSF seeding, CSF sampling after spine imaging via lumbar puncture is also necessary for staging. Molecular profiling is recommended, as identification of clinically relevant medulloblastoma subtypes (eg, SHH-activated) may encourage opportunities for clinical trial enrollment. Medulloblastoma should be staged according to the modified Chang system using information from both imaging and surgery.^{298,299}

Adjuvant Therapy

Patients should be stratified according to recurrence risk for planning of adjuvant therapy (reviewed by Brandes et al³⁰⁰). The NCCN Panel agrees that patients with large cell medulloblastoma, disease dissemination, unresectable tumors, or residual tumors greater than 1.5 cm² post-surgery are at heightened risk. These patients should undergo irradiation of the neuraxis and systemic therapy. Collection of stem cells before RT may be considered on the condition that RT is not delayed for potential future autologous stem cell reinfusion at disease progression. For patients at average risk, craniospinal RT with or without systemic therapy or reduced-dose craniospinal RT with systemic therapy followed by post-irradiation systemic therapy are viable options.

Recurrence and Progression

There are no robust data supporting an optimal follow-up schedule for medulloblastoma. Panel recommendations include brain MRI every 3 months for the first 2 years, every 6 to 12 months for 5 to 10 years, then every 1 to 2 years or as clinically indicated. If recurrent disease is detected on these scans, CSF sampling is also required, and concurrent spine imaging should be performed. Bone scans; contrast-enhanced CT scans

of the chest, abdomen, and pelvis; and bone marrow biopsies may be considered as indicated.

Maximal safe resection should be attempted for recurrent medulloblastoma if symptomatic and there is no evidence of dissemination. Additional options include systemic therapy alone and RT alone. High-dose chemotherapy with autologous stem cell rescue may be considered for patients showing no evidence of disease after conventional reinduction chemotherapy. Patients with metastases should be managed by systemic therapy or best supportive care, which can include palliative RT. In very select cases, intrathecal chemotherapy might be utilized.

Primary CNS Lymphomas

PCNSL accounts for approximately 3% of all neoplasms and 4% to 6% of all extranodal lymphomas.³⁰¹ It is an aggressive form of non-Hodgkin lymphoma that develops within the brain, spinal cord, eye, or leptomeninges without evidence of systemic involvement. The overall incidence of PCNSL in immunocompetent patients is 0.47 per 100,000 person-years, with higher incidence in males than in females and an increasing incidence with age.³⁰¹ The greatest increase in incidence has been reported in older adults with 1.8 per 100,000 patient-years reported in patients aged ≥65 years and 1.9 in patients aged ≥75 years, indicating that, in immunocompetent patients, PCNSL is a disease of older adults.^{301,302} Non-immunosuppressed patients have a better prognosis than AIDS-related cases,³⁰³ and survival of this group has improved over the years with treatment advances.^{304,305} For more guidance on treatment of patients with PCNSL who are living with HIV, see the NCCN Guidelines for Cancer in People with HIV (available at www.NCCN.org).

Pathologically, PCNSL is an angiocentric neoplasm composed of a dense monoclonal proliferation of lymphocytes, usually diffuse large B cells.³⁰⁶ More than 90% of these primary CNS diffuse large B-cell lymphoma cases

are of the activated B-cell–like (ABC) subtype.³⁰⁷ The tumor is infiltrative and typically extends beyond the primary lesion, as shown by CT or MRI scans, into regions of the brain with an intact BBB.³⁰⁷ The brain parenchyma is involved in more than 90% of all PCNSL patients, and the condition can be multifocal in more than 50% of cases. Leptomeningeal involvement may occur, either localized to adjacent parenchymal sites or in diffuse form (that is, positive cytology) in up to 30% of patients. Ocular involvement may develop independently in 10% to 20% of patients. Patients with PCNSL can present with various symptoms because of the multifocal nature of the disease. In a retrospective review of 248 immunocompetent patients, 43% had mental status changes, 33% showed signs of elevated intracranial pressure, 14% had seizures, and 4% suffered visual symptoms at diagnosis.³⁰⁸

PCNSL occurs in about 7% to 15% of patients with post-transplant lymphoproliferative disorders (PTLDs)³⁰⁹⁻³¹² and is associated with poor prognosis.^{311,313,314} PTLDs are a heterogeneous group of lymphoid neoplasms associated with immunosuppression following solid organ transplantation (SOT) or allogeneic hematopoietic stem cell transplantation (HCT).³¹⁵⁻³¹⁷ For guidance on managing transplant recipients, see the Post-Transplant Lymphoproliferative Disorders sub-algorithm in the NCCN Guidelines for Diffuse Large B-Cell Lymphoma (available at www.NCCN.org).

Treatment Overview

Steroid Administration

Steroids can rapidly alleviate signs and symptoms of PCNSL and improve PS. However, as these drugs are cytolytic, they can significantly decrease enhancement and size of tumors on CT and MRI scans as well as affect the histologic appearance. In the absence of significant mass effect, it is recommended that steroids be withheld or used judiciously until diagnostic tissue can be obtained if PCNSL is suspected.

Stereotactic Biopsy

In contrast to the principles previously outlined for invasive astrocytomas and other gliomas, the surgical goals for PCNSL are different, with the main goal being establishment of diagnosis under minimal risk of morbidity. Currently, most authors recommend biopsy rather than resection.³¹⁸ This approach stems from the fact that data do not demonstrate a survival advantage for patients who have had a complete resection or extensive STR when compared with those who have had only a stereotactic biopsy. In addition, STR is associated with risk for postoperative neurologic deficits.³⁰⁸

Systemic Therapy

Methotrexate is the most effective agent against PCNSL. It is commonly used in combination with other drugs such as procarbazine, vincristine, cytarabine, rituximab, and temozolomide.³¹⁹⁻³³³ High doses of intravenous methotrexate are necessary (≥ 3.5 g/m²) to overcome the BBB and achieve therapeutic levels in the CSF. Intrathecal methotrexate can be useful in select cases where CSF cytology yields positive findings and when patients cannot tolerate systemic methotrexate at 3.5 g/m² or higher. Other intrathecal chemotherapy options in this setting include cytarabine³³⁴ and rituximab.³³⁵ Phase II trials in the United States and Europe have shown that high-dose chemotherapy with autologous stem cell transplantation following high-dose methotrexate-based chemotherapy is feasible and well-tolerated, with little evidence of neurotoxicity.^{329,336-343}

Renal dysfunction induced by high-dose methotrexate therapy is a potentially lethal medical emergency due to heightened toxicities resulting from a delay in methotrexate excretion. Early intervention with glucarpidase, a recombinant bacterial enzyme that provides an alternative route for methotrexate clearance, has shown efficacy in rapidly reducing plasma concentrations of methotrexate and preventing severe toxicity.^{344,345}

Other regimens combined with methotrexate have been evaluated as induction therapy for PCNSL. The international randomized phase 2 MATRix trial randomized patients with newly diagnosed PCNSL (N = 219) into one of three study arms: 1) methotrexate and cytarabine; 2) methotrexate, cytarabine, and rituximab; and 3) methotrexate, cytarabine, rituximab, and thiotepa (MATRix).³⁴⁶ Complete response was more likely to have been achieved in the MATRix arm (49%; 95% CI, 38%–60%) compared to the methotrexate, cytarabine, and rituximab arm (30%; 95% CI, 21%–42%) and the methotrexate + cytarabine arm (23%; 95% CI, 14%–31%). In the multicenter international randomized HOVON study, patients with newly diagnosed PCNSL (N = 200) were randomized to receive methotrexate, carmustine, teniposide, and prednisolone with or without rituximab.³³³ OS at 1, 2, and 3 years was 79% (95% CI, 69%–86%), 65% (95% CI, 55%–74%), and 61% (95% CI, 51%–71%), respectively, for the arm that did not receive rituximab, and 79% (95% CI, 69%–85%), 71% (95% CI, 60%–79%), and 58% (95% CI, 46%–68%), respectively, for the arm that received rituximab. Limitations of these studies include selective inclusion criteria with exclusion of patients aged >70 years.^{333,346} The MATRix study showed that this regimen was associated with significant marrow toxicity.³⁴⁶ Other limitations of the HOVON study include use of consolidation WBRT in younger patients, which may not be tolerable in older patients; and only six doses of rituximab administered.³³³ Further, teniposide is not FDA approved for this indication and is no longer available in the United States. Methotrexate/carmustine/teniposide/prednisone with or without rituximab was subsequently removed from the Guidelines as an induction therapy option in 2022.

It has become clear that consolidative therapy can result in significant and sometimes lethal neurotoxic effects from consolidation RT, especially in patients >60 years of age.^{323,347,348} Complete response to chemotherapy ranges from 42% to 61%, with OS ranging between 14 and 55 months. A

number of phase II trials have adopted the approach of chemotherapy without planned RT.^{320,323,349-353} However, a high fraction of patients who have forgone initial RT—typically older or with significant comorbidities—may fail to achieve complete response to chemotherapy. Studies investigating the efficacy of methotrexate-based regimens as induction therapy for patients with PCNSL have utilized WBRT, including reduced WBRT following cytarabine as consolidation treatment.³²²⁻³²⁴

There are currently no conclusive prospective data published comparing consolidation with high-dose chemotherapy regimens or high-dose chemotherapy with autologous stem cell transplantation versus maintenance therapy or observation, and there are different approaches at different institutions. Consolidation with high-dose chemotherapy and autologous stem cell transplant is frequently considered for fitter patients. Eligibility criteria used in the respective trials that studied these regimens need to be carefully considered when considering this approach, and referral to centers with subspecialty expertise in PCNSL should be considered.

Cytarabine combined with etoposide as high-dose consolidation therapy following induction treatment with methotrexate, temozolomide, and rituximab was evaluated in the multicenter Alliance 50202 trial.³⁵⁴ This protocol was feasible and generally well-tolerated, with one treatment-related death.

High-dose chemotherapy with autologous stem cell transplantation in the relapsed/refractory setting has been tested with some success in two phase 2 European trials,^{355,356} although evidence of its advantage over conventional treatment is lacking. The German Cooperative PCNSL Study Group evaluated the safety and efficacy of rituximab, high-dose cytarabine, and thiotepa followed by autologous stem cell transplantation in 39 patients with relapsed or refractory PCNSL with previous high-dose methotrexate-based treatment.³⁵⁶ A complete response was achieved in

56% of the patients. Out of the remaining patients, only one had progressive disease (18% of the patients had a partial response or stable disease). However, median OS was not reached, with a 2-year OS rate of 56.4%. Median PFS was 12.4 months, with a 2-year PFS rate of 46%. A phase 2 trial from France evaluated the efficacy of high-dose cytarabine and etoposide followed by autologous stem cell transplantation in 43 patients with relapsed or refractory PCNSL with previous high-dose methotrexate-based treatment.³⁵⁵ Out of the 27 patients who completed autologous stem-cell rescue, median OS was 58.6 months (2-year OS was 69%) and median PFS was 41.1 months (2-year PFS was 58%).

High-dose chemotherapy and autologous stem cell transplantation as part of initial treatment has now been explored in several trials. High complete response rates and 2-year PFS have been demonstrated.^{329,357} Whether high-dose chemotherapy and autologous stem cell rescue provide any additional benefit over consolidative conventional-dose is being investigated in two trials currently in progress. Consolidative conventional-dose chemotherapy (NCTNA51101, MATRIX)³⁵⁸ or consolidative WBRT (ANOCEF-GOELAMS, IELSG32)³⁵⁹ have resulted in equivalent 2-year PFS in randomized phase II trials. Toxicities differ and might be a basis for individual patient selection. Of note, longitudinal neurocognitive assessment in the IELSG32 study showed persistent neurocognitive impairment in the consolidative WBRT group, but not in the high-dose chemotherapy group. Preliminary analysis of the NCTN A51101 trial showed a median PFS of 2.4 years for consolidative non-myeloablative chemotherapy, compared to a median PFS of 6 years after myeloablative consolidation, both following initial induction therapy.³⁶⁰ The extent to which the patient selection inherent in high-dose chemotherapy trials underlies these favorable outcomes remains to be determined.

Unfortunately, even for patients who initially achieved complete response, about half will eventually relapse. Re-treatment with high-dose

methotrexate may produce a second response in patients who achieved complete response with prior exposure.³⁶¹ Rituximab as well as ibrutinib may be used in combination with high-dose methotrexate retreatment.³⁶² Several other regimens, including ibrutinib,^{363,364} rituximab,³⁶⁵ TMZ with or without rituximab,³⁶⁶⁻³⁶⁹ lenalidomide with or without rituximab,³⁷⁰ high-dose cytarabine,³⁷¹ pomalidomide,³⁷² and pemetrexed³⁷³ have also shown activity in the relapsed/refractory disease setting, but none has been established as a standard of care.

Radiation Therapy

Historically, WBRT was the treatment standard to cover the multifocal nature of the disease. The majority of studies demonstrated the limitation of high-dose RT and led to the recommended dose of 24 to 36 Gy in 1.8 to 2.0 Gy fractions to the whole brain, without a boost.^{322,324,374-377} Although RT alone is useful for initial tumor control, frequent and rapid relapse of the disease led to a short OS of 12 to 17 months.^{303,376} This dismal outcome has prompted the addition of pre-irradiation methotrexate-based combination chemotherapy in later studies. This approach yields impressive response rates of up to 94% and improved OS ranging from 33 to 60 months.^{322-324,332,347,348,374,378,379} However, excessive grade 3 and 4 hematologic toxicity ($\leq 78\%$) as well as RT-induced delayed neurotoxicity ($\leq 32\%$) sometimes leading to deaths are primary concerns, although most of these studies utilized a high RT dose of greater than or equal to 40 Gy. Of note, younger patients (aged < 60 years) consistently fare better, and there is a higher incidence of late neurotoxic effects in older patients, but significant neurotoxicity can also occur in younger adults.

Thiel and colleagues³⁸⁰ conducted a randomized, phase III, non-inferiority trial of high-dose methotrexate plus ifosfamide with or without WBRT in 318 patients with PCNSL. There was no difference in OS (HR, 1.06; 95% CI, 0.80–1.40; $P = .71$), but the primary hypothesis (0.9 non-inferiority margin) was not proven. Patients who received WBRT had a higher rate of

neurotoxicity than those who did not (49% vs. 26%). The panel currently recommends that patients receiving WBRT because they are not candidates for chemotherapy should receive a dose of 24 to 36 Gy with a boost to gross disease, for a total dose of 45 Gy.

Although WBRT alone is seldom sufficient as primary treatment and is primarily reserved for patients who cannot tolerate multimodal treatment, it may be a reasonable treatment option for patients not suitable for other systemic therapies or clinical trials. Results from a phase II trial showed that reduced-dose WBRT (23.4 Gy in 1.8 Gy/fraction) following a complete response to induction chemotherapy was associated with disease response and long-term control, as well as low neurotoxicity.³⁸¹ When administered after chemotherapy failure, WBRT has shown response rates reaching nearly 75%.³⁸² Median PFS was 9.7 months overall, 57.6 months in patients who had achieved a CR with WBRT, and 9.7 months in patients with a PR. For patients who had a less than complete response to chemotherapy, a dosing schedule consistent with that used for induction treatment may be used, followed by a limited field to gross disease, or focal RT to residual disease.

NCCN Recommendations

Initial Evaluation

Neuroradiologic evaluation is important in the diagnosis of PCNSL and to evaluate the effectiveness of subsequent therapy. With MRI, the tumor is often isointense or hypointense on T1- and T2-weighted images and enhances frequently.³⁸³ In addition, restricted diffusion can be seen in the area of the enhancing abnormality on diffusion-weighted imaging sequences. On a CT scan, PCNSL is usually isodense or hyperdense compared to the brain and enhances in most cases. Hallmark features include a periventricular distribution, ring enhancement, multiple lesions, and a smaller amount of edema than might otherwise be expected from a similar-sized metastatic tumor or glioma. If contrast-enhanced brain MRI

(or contrast-enhanced CT if MRI is contraindicated) suggests PCNSL, clinicians are advised to hold the use of steroids if possible before diagnosis is established, since the imaging and histologic features of PCNSL can be profoundly affected by these drugs.

Patients with an enhancing brain lesion consistent with PCNSL should receive a biopsy (if lesion is amenable to biopsy), as this is the most direct and rapid route to achieve a pathologic diagnosis. Because the role of maximal surgical resection is limited to alleviating symptoms of raised intracranial pressure or preventing herniation,³⁰⁸ stereotactic biopsy is generally preferred to minimize invasiveness.³¹⁸ Even with molecular marker testing, however, a biopsy can occasionally be falsely negative, particularly if the patient had been treated previously with steroids. Thus, if a biopsy is nondiagnostic, the panel recommends that the steroids be tapered and that the patient be followed closely, both clinically and radiographically. If and when the lesion recurs, there should be a prompt repeat CSF evaluation or rebiopsy before the initiation of steroids. If, on the other hand, no definitive diagnosis of lymphoma is made from biopsy and the patient has not received steroid therapy, workup for other diagnoses (for example, inflammatory processes) or repeat CSF evaluation/rebiopsy is recommended. In some cases, diagnosis can be made by CSF analysis or by pathologic diagnosis of vitreoretinal disease.

Evaluation for Extent of Disease

Once the diagnosis of PCNSL is established, the patient should undergo a thorough staging workup detailed by The International PCNSL Collaborative Group.³¹⁸ This workup involves a complete CNS evaluation including imaging of the entire neuraxis (MRI of the spine with contrast). If possible, this should be done before CSF analysis is attempted to avoid post-lumbar puncture artifacts that can be mistaken for leptomeningeal disease on imaging.

A lumbar puncture with evaluation of CSF (15–20 mL of spinal fluid) should be considered, if it can be done safely and without concern for herniation from increased intracranial pressure, and if it will not delay diagnosis and treatment. A delay in treatment may compromise patient outcomes.³⁵⁴ Caution should be taken in patients who are anticoagulated, thrombocytopenic, or who have a bulky intracranial mass. CSF analysis should include flow cytometric analysis, CSF cytology, and cell count. The yield for a positive diagnostic test can be increased by the use of molecular markers of monoclonality, such as an immunoglobulin gene rearrangement.

Since disease is sometimes detected in the retina and optic nerve, a full ophthalmologic exam should be done, which should include a slit-lamp eye examination. In some cases, the diagnosis of lymphoma is made by vitrectomy; in this case, flow cytometric analysis is recommended. In addition, blood work (CBC and chemistry panel) and a contrast-enhanced body CT or PET/CT³⁸⁴ are required to rule out systemic involvement. Elevated lactate dehydrogenase (LDH) serum level is associated with worse survival in patients with PCNSL,^{385,386} and LDH should be evaluated as part of the workup for this disease. Bone marrow biopsy is a category 2B option that may be considered. In men >60 years of age, testicular ultrasound may be considered (category 2B). In these patients, regular testicular examination is encouraged. If both testicular examination and CT or PET/CT imaging are negative, then testicular ultrasound may not be necessary.

An HIV blood test should also be performed, because both prognosis and treatment of patients with HIV-related PCNSL may be different than that of patients who are otherwise immunocompetent. HIV-positive patients should receive highly active retroviral therapy in addition to their cancer therapy.

Newly Diagnosed Disease

Induction treatment should be initiated as soon as possible following confirmation of diagnosis. The International PCNSL Collaborative Group has published treatment response criteria for complete response, unconfirmed complete response, partial response, progressive disease, and relapsed disease.³¹⁸ Given the dramatic effect of steroids on symptom relief, they are commonly administered concurrently with workup. A high-dose methotrexate-containing regimen is the recommended induction treatment. In the case of methotrexate-induced renal dysfunction, consider glucarpidase to aid clearance. Non-methotrexate-based regimens may be used if the patient cannot tolerate methotrexate, usually those with impaired renal function.

If a patient is found to have malignant uveitis, orbital RT may be considered because of poor penetration of systemic chemotherapy into the uveal fluid. However, there are reports of clearance of ocular lymphoma in patients who were treated with systemic high-dose methotrexate.³²⁰ Therefore, for a patient with PCNSL who has asymptomatic ocular involvement, a reasonable strategy is to delay RT to the globe in order to see if high-dose methotrexate is effective. Referral to a neuro-ophthalmologist or ophthalmologic oncologist for intraocular injection of chemotherapy (category 2B) is also an option.

WBRT may be used in patients who are not candidates for chemotherapy. For a patient treated with WBRT, consideration of intra-CSF chemotherapy plus focal spinal RT are treatment options if the lumbar puncture or spinal MRI are positive. Intrathecal chemotherapy options include methotrexate, cytarabine, and rituximab.

Treatment following induction high-dose methotrexate-based therapy depends on disease response.³¹⁸ Given the rarity of this disease, there are few high-quality studies to inform treatment decision-making. For patients who have a complete or unconfirmed complete response, consolidation

therapy options that may be considered include high-dose chemotherapy (cytarabine/thiotepa followed by carmustine/thiotepa; or thiotepa/busulfan/cyclophosphamide [TBC]) with stem cell rescue^{329,336-342} or low-dose WBRT. However, WBRT in this setting may increase neurotoxicity,^{380,387} especially in patients >60 years.^{323,347,348} High-dose cytarabine with or without etoposide is also a consolidation treatment option for patients who had a complete response to induction high-dose methotrexate-based therapy (this regimen may also be considered in patients who do not have a complete response).^{322-324,354} If there is not a complete or unconfirmed complete disease response following induction therapy, it is recommended to pursue another systemic therapy or WBRT in order to rapidly induce a response, diminish neurologic morbidity, and optimize quality of life. Best supportive care is another option for patients with residual disease following methotrexate-based treatment who are not candidates for other reasonable rescue therapies.

Relapsed or Refractory Disease

Patients should be followed using brain MRI. Imaging of the spine and CSF sampling may be done as clinically indicated for patients with spine disease. If there is ocular involvement, ophthalmologic exams may also be carried out.

For patients who are treated with prior WBRT and ultimately relapse, they may consider further chemotherapy (systemic and/or intrathecal), focal reirradiation, or palliative/best supportive care.

For patients who were initially treated with high-dose methotrexate-based chemotherapy but did not receive WBRT, the decision about whether to use other systemic therapy or proceed to RT at the time of relapse depends on the duration of response to initial chemotherapy. If a patient had experienced a relatively long-term response of about one year or more, then treating either with the same (in most cases, high-dose methotrexate-based therapy) or another regimen is reasonable. However,

for patients who either have no response or relapsed within a very short time after systemic therapy, recommendations include switching to a different chemotherapy regimen, or WBRT, or involved-field RT with or without chemotherapy.³⁸² In either case, palliative/best supportive care remains an option.

High-dose chemotherapy with stem cell rescue may also be considered as treatment for relapsed/refractory disease in patients who did not previously receive this treatment (ie, patients who were treated with high-dose methotrexate-based therapy or with WBRT) (category 2B). Regardless of primary treatment received, stem cell rescue should only be used for relapsed/refractory disease if there is a complete or partial response to re-induction high-dose chemotherapy.

For patients previously treated with high-dose chemotherapy with stem cell rescue, retreatment may be considered if there was a previous disease response and if time to relapse was at least one year. For patients who did not have a response to high-dose chemotherapy with stem cell rescue, and the time to relapse was less than one year, treatment options include RT to the whole brain or to the involved field. Regardless of time to relapse, using a different systemic therapy regimen (without stem cell rescue) and best supportive care are also options.

As there is no uniform standard of care for the treatment of refractory or relapsed PCNSL, participation in clinical trials is encouraged.

Primary Spinal Cord Tumors

Spinal tumors are classified according to their anatomic location as extradural, intradural-extramedullary, and intradural-intramedullary. Extradural tumors are primarily due to metastatic disease and are discussed in the section *Metastatic Spinal Tumors*. This section focuses on intradural primary spinal tumors.

Primary spinal cord tumors are a histologically diverse set of diseases that represent 2% to 4% of all primary CNS tumors. The overall incidence is 0.74 per 100,000 person-years with a 10-year survival rate of 64%.³⁸⁸ Extramedullary lesions, most commonly benign meningiomas, account for 70% to 80% of spinal cord tumors.³⁸⁹ Astrocytomas (more prevalent in children) and ependymomas (more prevalent in adults) are the most common intramedullary tumors. Clinicians are advised to refer to the corresponding sections in these guidelines for further details regarding these subtypes, as intracranial and spinal lesions are biologically similar.

Individuals with type I neurofibromatosis, type II neurofibromatosis, and von Hippel-Lindau (VHL) syndrome are predisposed to form, respectively, spinal astrocytomas, spinal peripheral nerve sheath tumors, spinal ependymomas, and intramedullary hemangioblastomas.

Since 70% of primary spinal cord tumors are low-grade and slow-growing,³⁸⁸ it is common for patients to suffer from pain for months to years before diagnosis. Pain that worsens at night is a classic symptom for intramedullary lesions. Progressive motor weakness occurs in half of the patients, and patients may experience sensory loss with late autonomic dysfunction (incontinence).

Treatment Overview

Observation

Many asymptomatic primary tumors of the spinal cord, especially grade 1 meningiomas and peripheral nerve sheath tumors, follow an indolent course and can be followed by observation without immediate intervention.

Surgery

Surgery is the preferred primary treatment when the tumor is symptomatic and amenable to surgical resection. For lesions that are radiographically well defined, such as ependymoma, WHO grade 1 astrocytoma, hemangioblastoma, schwannoma, and WHO grade 1 meningioma,

potentially curative, maximal, safe resection is the goal. En bloc total resection yielded excellent local control rates of more than 90%.³⁹⁰⁻³⁹³

GTR is seldom feasible with grade 2 or higher astrocytomas because they are infiltrative and poorly circumscribed. In a study of 202 patients with intramedullary tumors, over 80% of grade 1 astrocytomas were completely resected, while total resection was achieved in only 12% of grade 2 tumors.³⁹⁴ Nevertheless, Benes et al³⁹⁵ conducted a review of 38 studies on spinal astrocytomas and concluded that maximal safe resection should be attempted whenever possible based on reports of survival benefit.

Radiation Therapy

RT is not recommended as the primary therapy without surgery and unknown histology because of the potential for limited response and low RT tolerance of the spinal cord. It is also not advisable following GTR of certain histologies, as select spinal cord tumors that can be excised completely have a low local recurrence rate.

A large retrospective analysis including more than 1700 patients with primary spinal gliomas found an association between RT and worse cause-specific survival and OS, although there may be a bias that patients who received RT had more adverse factors.³⁹⁶ The role of adjuvant RT following incomplete excision or biopsy remains controversial.^{395,397,398} One exception is primary spinal myxopapillary ependymoma, for which postoperative RT has been demonstrated to reduce the rate of tumor progression.^{399,400} On the other hand, EBRT is considered a viable option at disease progression or recurrence. SRS has also shown safety and efficacy in several patient series, including patients with spinal cord hemangioblastoma.⁴⁰¹⁻⁴⁰⁴

Systemic Therapy

Unfortunately, evidence on efficacious chemotherapeutic agents for primary spinal cord tumors is too scant for specific recommendations. The

panel agrees that systemic therapy should be an option where surgery and RT fail, but there is no consensus on the best regimen. Systemic therapy is best given in the setting of a clinical trial.

In August 2021, the FDA approved the HIF-2alpha inhibitor belzutifan for the treatment of patients with VHL-associated CNS hemangioblastomas not requiring immediate surgery. Approval was based on results of a nonrandomized phase 2 trial that included patients with VHL-associated renal cell carcinoma (N = 61).⁴⁰⁵ Objective response in patients with CNS hemangioblastoma was 30% (n = 50).

NCCN Recommendations

MRI imaging is the gold standard for diagnosis of spinal cord lesions. However, CT myelogram may be used for diagnosis in patients for whom MRI is contraindicated. Asymptomatic patients may be observed (especially for suspected low-grade) or resected, while all symptomatic patients should undergo some form of surgery. The surgical plan and outcome are influenced by whether a clear surgical plan is available.⁴⁰⁶ Whenever possible, maximal safe resection should be attempted, with a spine MRI 2 to 3 weeks following surgery to assess the extent of the resection. Postoperative adjuvant RT is appropriate if symptoms persist after incomplete resection or biopsy, or for patients with myxopapillary ependymoma that has been incompletely resected. Patients should be managed according to the pathology results (see *Low-Grade Gliomas, High-Grade Gliomas [Including Glioblastoma], and Intracranial and Spinal Ependymomas*). Those diagnosed with hemangioblastoma should consider screening for VHL syndrome including neuraxis imaging.⁴⁰⁷

All patients should be followed by sequential MRI scans, with a greater frequency in patients with high-grade tumors. At progression or recurrence, re-resection is the first choice. If this is not feasible, conventional EBRT is the next option. Systemic therapy is reserved for

cases where both surgery and RT are contraindicated. Specific regimens are dependent on primary tumor type. Belzutifan is a systemic therapy option for patients with VHL-associated CNS hemangioblastoma not requiring immediate surgery.⁴⁰⁵

Meningiomas

Meningiomas are extra-axial CNS tumors arising from the arachnoid cap cells in the meninges. They are most often discovered in middle-to-late adult life, and have a female predominance. The annual incidence for males and females reported by the Central Brain Tumor Registry of the United States (CBTRUS) are 1.8 and 3.4 per 100,000 people, respectively.⁴⁰⁸ In a review of 319 cases using the WHO grading scale, 92% of meningiomas are WHO grade 1, 6% are grade 2 (atypical), and 2% are grade 3.⁴⁰⁹ Small tumors are often asymptomatic, incidental findings.⁴¹⁰ Seizure is a common presenting symptom occurring in 27% of patients.⁴¹¹

Imaging

Brain imaging with contrast-enhanced CT or MRI is the most common method of diagnosing, monitoring, and evaluating response to treatment (review by Campbell et al⁴¹²). The CT scan best reveals the chronic effects of slowly growing mass lesions on bone remodeling. Calcification in the tumor (seen in 25%) and hyperostosis of the surrounding skull are features of an intracranial meningioma that can be easily identified on a non-contrast CT scan. Nonetheless, MRI reveals a number of imaging characteristics highly suggestive of meningioma, and in SRS articles, MR has been used to operationally define pathology. These MR findings include a tumor that is dural-based and isointense with gray matter, demonstrates prominent and homogeneous enhancement (>95%), has frequent CSF/vascular cleft(s), and often has an enhancing dural tail (60%). However, approximately 10% to 15% of meningiomas have an atypical MRI appearance mimicking metastases or malignant gliomas. In

particular, secretory meningiomas may have a significant amount of peritumoral edema. Cerebral angiography is occasionally performed, often for surgical planning, as meningiomas are vascular tumors prone to intraoperative bleeding. In some instances preoperative embolization is helpful for operative hemostasis management. Angiographic findings consistent with a meningioma include a dual vascular supply with dural arteries supplying the central tumor and pial arteries supplying the tumor periphery. A “sunburst effect” may be seen due to enlarged and multiple dural arteries, and a prolonged vascular stain or so-called “blushing” can be seen, which results from intratumoral venous stasis and expanded intratumoral blood volume.

Meningiomas are also known to have high somatostatin receptor density, which allows for the use of octreotide brain scintigraphy to help delineate extent of disease and to pathologically define an extra-axial lesion.⁴¹³⁻⁴¹⁵ Octreotide imaging with radiolabeled indium or, more recently, gallium may be particularly useful in distinguishing residual tumor from postoperative scarring in subtotally resected/recurrent tumors.

Treatment Overview

Observation

Studies that examined the growth rate of incidental meningiomas in otherwise asymptomatic patients suggested that many asymptomatic meningiomas may be followed safely with serial brain imaging until either the tumor enlarges significantly or becomes symptomatic.^{416,417} These studies confirm the tenet that many meningiomas grow very slowly and that a decision not to operate is justified in selected asymptomatic patients. As the growth rate is unpredictable in any individual, repeat brain imaging is mandatory to monitor an incidental asymptomatic meningioma.

Surgery

The treatment of meningiomas is dependent upon both patient-related factors (ie, age, PS, medical comorbidities) and treatment-related factors (ie, reasons for symptoms, resectability, goals of surgery). Most patients diagnosed with surgically accessible symptomatic meningioma undergo surgical resection to relieve neurologic symptoms. Complete surgical resection may be curative and is therefore the treatment of choice, if feasible. Both the tumor grade and the extent of resection impact the rate of recurrence. In a cohort of 581 patients, 10-year PFS was 75% following GTR but dropped to 39% for patients receiving STR.⁴¹⁸ Short-term recurrences reported for grade 1, 2, and 3 meningiomas were 1% to 16%, 20% to 41%, and 56% to 63%, respectively.⁴¹⁹⁻⁴²¹ The Simpson classification scheme that evaluates meningioma surgery based on extent of resection of the tumor and its dural attachment (grades 1–5 in decreasing degree of completeness) correlates with local recurrence rates.⁴²² First proposed in 1957, it is still being widely used by surgeons today.

Radiation Therapy

Safe GTR is sometimes not feasible due to tumor location. In this case, SRS followed by adjuvant EBRT has been shown to result in long-term survival comparable to GTR (86% vs. 88%, respectively), compared to only 51% with incomplete resection alone.⁴²³ Of 92 patients with grade 1 tumors, Soyuer and colleagues found that RT following SRS reduced progression compared to incomplete resection alone, but has no effect on OS.⁴²⁴ Conformal fractionated RT (eg, 3D-CRT, IMRT, VMAT, proton therapy) may be used in patients with grade 1 meningiomas to spare critical structures and uninvolved tissue.⁴²⁵

Because high-grade meningiomas have a significant probability of recurrence even following GTR,⁴²⁶ postoperative high-dose EBRT (>54 Gy) has become the accepted standard of care for these tumors to

improve local control.⁴²⁷ Initial results of the phase II RTOG 0539 trial showed that patients with high-risk meningioma treated with IMRT (60 Gy in 30 fractions) had a 3-year PFS rate of 58.8%.⁴²⁸ High risk was defined as new or recurrent grade 3, recurrent grade 2, or new grade 2 with SRS. Since new and recurrent tumors were grouped together, this study does not provide clarification on the appropriate role of RT following GTR in patients with newly diagnosed WHO grade 2 disease, and the role of post-GTR RT in these cases remains controversial.

The use of SRS (either single fraction or fractionated) in the management of meningiomas continues to evolve. Advocates have suggested this therapy in lieu of EBRT for small (<35 mm), recurrent, or partially resected tumors. In addition, it has been used as primary therapy in surgically inaccessible tumors (ie, base-of-skull meningiomas) or in patients deemed poor surgical candidates because of advanced age or medical comorbidities. Nonrandomized and retrospective studies show that SRS is associated with excellent tumor control and good survival outcomes, particularly in grade 1 tumors, indicating that this treatment is effective as primary and second-line treatment for meningiomas smaller than 3.5 cm.⁴²⁹⁻⁴³³ However, optimal dosing has not been determined. SRS may also be considered in carefully selected patients with grade 2 meningiomas, such as those with recurrent disease.^{434,435}

Systemic Therapy

For meningiomas that recur despite surgery and/or RT, or are not amenable to treatment with surgery or RT, systemic therapies are often considered. Due to the rarity of these patients requiring systemic therapy, large randomized trials are lacking. Historical estimates of 6-month PFS rates in these patients range from 0% to 29%.⁴³⁶ Smaller studies support the use of targeted therapy including somatostatin analogues in select cases.^{437,438} Studies investigating anti-angiogenic therapies in meningioma have also demonstrated improved results.

A prospective, multicenter, nonrandomized, phase II trial evaluating the safety and efficacy of sunitinib in 36 heavily pretreated patients with refractory meningioma showed a 6-month PFS rate of 42%, with a median PFS rate of 5.2 months and a median OS rate of 24.6 months.⁴³⁹ However, toxicities were considerable, with 60% of patients experiencing grade 3 or higher toxicity.

Retrospective data support the use of bevacizumab for patients with recurrent meningioma, especially for patients with symptoms driven by RT necrosis, with a 6-month PFS rate of 43.8% for recurrent surgery and radiation-refractory grade 2 and 3 meningioma with bevacizumab monotherapy.^{440,441} In a phase II trial evaluating the efficacy and safety of bevacizumab combined with everolimus for recurrent meningioma ($N = 17$), stable disease was reported in 88% of patients, with no complete or partial responses reported.⁴⁴² The median PFS and OS rates were 22.0 months and 23.8 months, respectively, with 18-month PFS and OS rates of 57% and 69%, respectively. Treatment was discontinued in 22% of patients due to toxicity.

NCCN Recommendations

Initial Treatment

Meningiomas are typically diagnosed by brain MRI. Surgery or octreotide scan may be considered for confirmation. For treatment planning, multidisciplinary panel consultation is encouraged. Patients are stratified by the presence or absence of symptoms and the tumor size. Most asymptomatic patients with small tumors (≤ 3 cm) are best managed by observation; otherwise, patients should undergo surgical resection whenever possible. Non-surgical candidates should undergo RT.

Regardless of tumor size and symptom status, all patients with surgically resected grade 3 meningioma (even after GTR) should receive adjuvant RT to enhance local control. For patients with grade 2 meningioma,

postoperative RT is recommended for incomplete resection, though observation is an option in select patients (eg, those unfit for RT). In the case of complete resection in patients with grade 2 meningioma, postoperative RT may be considered, although this treatment strategy remains controversial. Patients with grade 1 meningioma may be observed following surgery, though postoperative RT may be considered in patients with symptomatic disease. SRS may be used in lieu of conventional RT as adjuvant or primary therapy in asymptomatic cases.

Follow-up and Recurrence

In the absence of data, panelists have varying opinions on the best surveillance scheme and clinicians should follow patients based on individual clinical conditions. Generally, malignant or recurrent meningiomas are followed more closely than grade 1 and 2 tumors. A typical schedule for low-grade tumors is MRI every 3 months in year 1, then every 6 to 12 months for another 5 years. After 5 years, imaging may be done every 1 to 3 years as clinically indicated.

Upon detection of recurrence, the lesion should be resected whenever possible, followed by RT. Non-surgical candidates should receive RT. Systemic therapy is reserved for patients with an unresectable recurrence refractory to RT. Observation is an option if there is no clinical indication for treatment at recurrence.

Brain Metastases

Metastases to the brain are the most common intracranial tumors in adults and may occur up to 10 times more frequently than primary brain tumors. Population-based data reported that about 8% to 10% of patients with cancer are affected by symptomatic metastatic tumors in the brain.^{443,444} Based on autopsy studies, brain metastases have been shown to be present in 25% of patients with cancer.⁴⁴⁵

As a result of advances in diagnosis and treatment, many patients improve with proper management and do not die of progression of these metastatic lesions. Primary lung cancers are the most common source,⁴⁴⁶ and melanoma has the highest rates of brain metastases among patients with metastatic disease.^{447,448} Diagnosis of CNS involvement is increasing in patients with breast cancer as therapy for metastatic disease is improving.⁴⁴⁹

Nearly 80% of brain metastases occur in the cerebral hemispheres, an additional 15% occur in the cerebellum, and 5% occur in the brainstem.⁴⁵⁰ Parenchymal lesions typically follow a pattern of hematogenous spread to the gray-white junction where the relatively narrow caliber of the blood vessels tends to trap tumor emboli. Patients with brain metastases may present with a single or solitary metastasis or numerous lesions present on MRI. With improved detection and higher resolution of brain MRI, metastases can now be detected at sizes in the 2- to 3-mm range. Patients may be diagnosed with brain metastases on screening MRI without any symptoms. Among patients with symptomatic brain metastases, presenting symptoms may be similar to those of other mass lesions in the brain, such as headache, nausea, seizures, and neurologic impairment.

Treatment Overview

Surgery

Despite advances in surgical techniques, surgery alone for brain metastases results in unacceptable local control rates and adjuvant RT, discussed below, is appropriate to consider.^{451,452} The objectives of surgery for brain metastasis include retrieval of tissue for diagnosis, reduction of mass effect, and improvement of edema.⁴⁵³ Randomized trials reported in the 1990s demonstrated an OS benefit with surgical resection for patients with single brain metastases. In a study of 48 patients, Patchell et al⁴⁵⁴ demonstrated that surgery followed by WBRT compared

with WBRT alone improved OS (40 vs. 15 weeks in WBRT arm; $P < .01$) and functional dependence (38 vs. 8 weeks; $P < .005$), as well as decreased recurrence (20% vs. 52%; $P < .02$). Similarly, adding surgery to WBRT led to longer survival and functional independence compared to WBRT alone in another randomized study by Vecht and colleagues (n = 63).⁴⁵⁵ A third study of 84 patients found no difference in survival between the two strategies; however, patients with extensive systemic disease and lower performance level were included, which likely resulted in poorer outcomes in the surgical arm.⁴⁵⁶

For patients with recurrent brain metastases or radiation necrosis who are poor surgical candidates, laser interstitial thermal ablation may represent a reasonable less invasive treatment option.⁴⁵⁷⁻⁴⁶¹ Advantages of laser thermal ablation include rapid discharge from the hospital (within 24–48 hours) and avoidance of stay in the intensive care unit (ICU), rehabilitation facility, or other extended care facility.

Stereotactic Radiosurgery

SRS offers an excellent minimally invasive ablative treatment option for brain metastases. Patients undergoing SRS avoid the risk of surgery-related morbidity, and SRS is generally preferred over surgery for patients with small, asymptomatic lesions that do not require surgery and for patients with lesions that are not surgically accessible.⁴⁵³ Late side effects of SRS such as symptomatic edema and RT necrosis are relatively uncommon, but may be observed at higher rates when treating larger lesions or at higher doses.⁴⁶²

The role of stereotactic SRS alone for limited brain metastases has been established by multiple phase III randomized trials comparing SRS alone to SRS plus WBRT.⁴⁶³⁻⁴⁶⁶ Collectively, these studies demonstrate comparable OS and superior cognitive preservation and quality of life with SRS alone compared to SRS plus WBRT. The role of SRS for patients with multiple metastases has also continued to expand. A prospective trial

of 1194 patients found no differences in OS or neurologic mortality with SRS for 2 to 4 versus 5 to 10 brain metastases.⁴⁶⁷ A number of analyses have suggested that total volume of brain metastases and the rate of developing new brain metastases may be more important prognostic factors for OS than the number of discrete brain metastases.⁴⁶⁸⁻⁴⁷¹ Taken together, patients with multiple lesions but a low total volume of disease, as well as those with relatively indolent rates of developing new CNS lesions, can represent suitable candidates for SRS. Additionally, patients with a favorable histology of the primary tumor (such as breast cancer) or controlled primary tumors may benefit from a strategy of SRS regardless of the number of brain metastases present.^{472,473} While brain metastases arising from small cell lung cancer have historically been treated with WBRT, a large international retrospective study and a subsequent meta-analysis of retrospective studies suggested that SRS may be suitable in some cases.^{474,475} Brain metastases in patients with radio-resistant primary tumors such as melanoma and renal cell carcinoma can achieve good local control with SRS.⁴⁷⁶ Other predictors of longer survival with SRS include younger age, good PS, and primary tumor control.^{468,472,473,477} However, there are a number of contemporary series supporting SRS in patients with a poor prognosis, with poor KPS, or who are older.⁴⁷⁸⁻⁴⁸¹ A systematic review including 32 retrospective studies showed that SRS is also safe and effective in patients with metastases of the brainstem.⁴⁸²

Maximal marginal doses for SRS use should be based on tumor volume and location in the brain, and doses range from 15 to 24 Gy when treating lesions with a single fraction of SRS.^{463,467,483,484} For large metastases, local control is generally low, and radionecrosis risk is high with single-fraction SRS.⁴⁸⁵ Multi-fraction SRS may be considered for larger tumors, with the most common doses being 27 Gy in 3 fractions and 30 Gy in 5 fractions.⁴⁸⁶⁻⁴⁸⁸ In the recurrence setting, several patient series have demonstrated local control rates greater than 70% with SRS for patients with good PS and stable disease who have received prior WBRT.⁴⁸⁹⁻⁴⁹²

Postoperative SRS also represents an important strategy to improve local control after resection of brain metastases. After resection alone, the rates of local recurrence are relatively high, and have been reported in the range of 50% at 1 to 2 years in prospective trials. Postoperative SRS to the surgical cavity is supported by a randomized phase III trial including 132 patients with resected brain metastases (1–3 lesions). This trial demonstrated that postoperative SRS was associated with a higher 12-month local recurrence-free rate compared to no postoperative treatment (72% vs. 43%, respectively; HR, 0.46; 95% CI, 0.24–0.88; $P = .015$).⁴⁵¹ A separate randomized phase III trial comparing postoperative SRS with postoperative WBRT demonstrated similar OS and better cognitive preservation with a strategy of postoperative SRS, despite superior CNS control outcomes with WBRT.⁴⁹³ Contouring guidelines for postoperative SRS have been published elsewhere.⁴⁹⁴

Whole-Brain Radiation Therapy

Historically, WBRT was the mainstay of treatment for metastatic lesions in the brain. Although the role of WBRT has diminished over the last several decades, WBRT continues to play a role in the modern era, primarily in clinical scenarios where SRS and surgery are not feasible or indicated (eg, diffuse brain metastases, high brain metastasis velocity, leptomeningeal disease). The standard dosing for WBRT is 30 Gy in 10 fractions, as supported by the CC001 study.⁴⁹⁵ There is limited evidence to support more protracted WBRT regimens longer than 10 fractions, especially as quality of life may be impacted with longer fractionation schemes beyond 10 fractions. For patients with poor prognoses and symptomatic brain metastases, 20 Gy in 5 fractions may also be used.

The impact of WBRT in addition to SRS has been evaluated in multiple randomized controlled studies.^{463-466,496} A 2018 Cochrane meta-analysis of randomized controlled trials found that the addition of WBRT to SRS alone was associated with better CNS disease control outcomes, no differences

in OS, and worse neurocognitive outcomes or quality of life in several trials.⁴⁹⁷ The randomized phase III EORTC 22952 trial failed to show an OS benefit from WBRT following resection or SRS, compared to observation,⁴⁶⁶ even in subgroup analyses including only patients with controlled extracranial disease and a favorable prognostic score.⁴⁹⁸ Overall, for patients treated with SRS for brain metastases, the routine addition of WBRT is not recommended due to increased cognitive and quality-of-life toxicity and the lack of an OS benefit. Conversely, results from the randomized phase III RTOG 9508 trial showed that an SRS boost could improve local control in select patients (eg, large lesions or radioresistant histology) already receiving WBRT.⁴⁹⁶

The randomized phase III non-inferiority QUARTZ trial compared WBRT to optimal supportive care in patients with non-small cell lung cancer (NSCLC) who were not candidates for SRS, due to various factors including age, PS, and extent of disease. No differences in OS or quality of life were observed with WBRT versus optimal supportive care, which suggests that this population may derive minimal benefit from WBRT.⁴⁹⁹ Moreover, as noted above, a number of studies support SRS for older patients and those with poor prognosis who have historically received WBRT.^{478-481,500} The optimal treatment strategy for brain metastases for patients with a poor prognosis is highly individualized and may call for best supportive care, WBRT, SRS, or trials of CNS-active systemic agents depending on the clinical scenarios.

In light of the well-characterized deleterious cognitive effects of WBRT,^{464,465,493} a number of trials have evaluated strategies to promote cognitive preservation in patients with brain metastases including investigation of neuroprotective agents, anatomical avoidance strategies, and deferral of WBRT in favor of alternate strategies such as SRS or trials of CNS-active systemic agents. In patients undergoing WBRT for brain metastases, the RTOG 0614 ($N = 554$) compared concurrent and adjuvant

memantine, an N-methyl-D-aspartate receptor antagonist, to placebo. Memantine was well-tolerated in patients receiving WBRT for brain metastases, and the rates of toxicity were similar to patients receiving placebo.⁵⁰¹ There was a trend toward less decline in episodic memory (HVLT-R Delayed Recall) in the memantine arm compared to placebo at 24 weeks ($P = .059$). The memantine arm had significantly longer time to cognitive decline (HR, 0.78; 95% CI, 0.62–0.99; $P = .01$), and the probability of cognitive function failure at 24 weeks was 54% in the memantine arm and 65% in the placebo arm. However, for most cognitive endpoints, no significant differences were observed between memantine and placebo, despite numerical trends that generally favored the memantine arm. For patients with a favorable prognosis, consideration of memantine during WBRT and for up to 6 months afterward is recommended.

To evaluate an anatomic-avoidance strategy to promote cognitive preservation, the single-arm phase II RTOG-0933 trial showed that reduced radiation dose to the hippocampal neural stem-cell compartment was associated with a smaller decline in recall ($P < .001$) compared to a historical control.⁵⁰² Based on these results, the phase III NRG-CC001 trial evaluated WBRT with memantine with or without hippocampal avoidance (HA).⁴⁹⁵ There were no significant differences in survival outcomes. However, risk of cognitive failure was significantly lower in the HA arm than in the control arm (HR, 0.76; 95% CI, 0.60–0.98; $P = .03$). For patients with a favorable prognosis (≥ 4 months), without brain metastases within 5 mm of the hippocampus or leptomeningeal disease, HA-WBRT plus memantine is the preferred approach for delivering WBRT.

In the postoperative setting, phase 3 trials have evaluated the role of WBRT after surgical resection of brain metastases. Patchell conducted a study that randomized 95 patients with single intracranial metastases to surgery with or without adjuvant WBRT.⁵⁰³ Postoperative RT was

associated with a dramatic reduction in tumor recurrence (18% vs. 70%; $P < .001$) and likelihood of neurologic deaths (14% vs. 44%; $P = .003$). OS, a secondary endpoint, showed no difference between the arms. The aforementioned EORTC 22952 trial randomized patients treated with local therapy (surgery or SRS) to observation versus WBRT.⁴⁶⁶ Patients randomized to WBRT were found to have superior brain disease control and less death from neurological causes, but inferior quality of life and no differences in OS.^{466,504} The NCCTG N107C/CEC-3 randomized phase III trial included 194 patients with resected brain metastases randomized to either postoperative SRS or WBRT.⁴⁹³ Although there was no significant difference between the treatment arms for OS, cognitive deterioration at 6 months was less frequent in the SRS arm than in the WBRT arm (52% vs. 85%, respectively; $P < .001$), and cognitive deterioration-free survival was also superior for postoperative SRS compared to WBRT (median 3.7 months vs. median 3.0 months; HR, 0.47; 95% CI, 0.35–0.63; $P < .001$). In another phase III trial, 215 patients with 1 to 3 brain metastases from melanoma were randomized to either WBRT or observation following local treatment with surgery or SRS.⁵⁰⁵ Although the local failure rate was significantly lower in the WBRT arm (20.0% vs. 33.6%, respectively; $P = .03$), there were no significant differences between the study arms for intracranial failure, OS, and deterioration in performance status. Further, grade 1 to 2 toxicity during the first 2 to 4 months was more frequently reported in the WBRT arm.

Systemic Therapy

Many tumors that metastasize to the brain are not chemosensitive or have already been heavily pretreated with organ-specific effective agents. Poor penetration through the BBB is an additional concern.⁴⁴⁷ However, there are increasing numbers of systemic treatment options with demonstrated activity in the brain, and it is now reasonable to treat some of these patients (ie, those with asymptomatic brain metastases) with systemic therapy upfront instead of upfront SRS or WBRT.

Specific recommended regimens for brain metastases are based on effective treatment of the primary tumor (see below). However, there is also an increasing number of “basket” studies that evaluate the efficacy of targeted therapy options for a specific mutation or biomarker, regardless of tumor type. For example, the TRK inhibitors larotrectinib and entrectinib were found to be active in patients with brain metastases from *NTRK* gene fusion-positive solid tumors.^{98,99}

As CNS-active systemic agents are changing paradigms for the management of brain metastases, it is important to acknowledge that there is a paucity of prospective data to characterize optimal strategies regarding radiation and systemic therapy combinations or sequencing. When considering a trial of upfront systemic therapy alone for brain metastases, a multidisciplinary discussion between medical and radiation oncology is recommended. Ongoing CNS surveillance with brain MRIs is essential to allow early interventions in cases of progression or inadequate response.

Melanoma

Rapid advancements in melanoma have produced effective systemic options for metastatic disease.^{506,507} These include multiple immunotherapy options. Two phase II trials support the use of a combination of the immunotherapy agents ipilimumab and nivolumab for patients with asymptomatic untreated brain metastases from melanoma.⁵⁰⁸⁻⁵¹⁰ In one of these trials, which was conducted in Australia, intracranial responses were observed in 46% of patients who received this combination, with a complete response observed in 17% ($n = 79$), and median duration of response was not reached at the time of publication (median 14 months of follow-up).⁵⁰⁸ In the second trial, CheckMate 204, the intracranial response was 57.4%, with a complete response of 33% ($N = 101$).⁵¹⁰ The median duration of intracranial response was not reached at time of publication, with 58% of responses lasting more than 2 years.

Intracranial 36-month PFS and OS were 54.1% and 71.9%, respectively. Limited disease response was observed in patients with symptomatic disease, though this could potentially have been attributed to corticosteroid use. In both of these trials, grade 3 or 4 treatment-related adverse events occurred in just over half of the patients evaluated.^{508,510} Results from the Australian trial also suggest there may be a role for nivolumab monotherapy for patients with asymptomatic untreated brain metastases ($n = 27$), with an intracranial response rate of 20%.⁵⁰⁸ For patients with asymptomatic untreated lesions, the response rate for patients who received ipilimumab/nivolumab was better than for nivolumab monotherapy. This trial also evaluated nivolumab monotherapy for a small number of patients for whom local therapy failed ($n = 16$), but the intracranial response rate was low (6%). A nonrandomized phase II study supports ipilimumab monotherapy for patients with small asymptomatic brain metastases from melanoma ($n = 51$), with a CNS disease control rate of 24% (no complete responses).⁵¹¹ Most of the patients in this study had received previous systemic or local treatment. Nivolumab monotherapy is a reasonable treatment option for a carefully monitored patient whose goal is to avoid radiation.

The anti-PD-1 antibody pembrolizumab is also supported for treatment of both untreated and progressive brain metastases from melanoma, based on early results of a phase II trial showing a CNS ORR of 22% ($n = 18$).⁵¹² Long-term follow-up from this trial showed a CNS response in 26% of the sample ($N = 23$), with four complete responses.⁵¹³ In patients who had a CNS response, these responses were ongoing at 24 months in all of the patients. Median PFS and OS were 2 months and 17 months, respectively. Grade 3–4 treatment-related adverse events were minimal. Despite data showing that brain metastases can respond to immune checkpoint inhibitors, the data do not yet provide any robust comparison of these agents from treatment of brain metastases from melanoma.

There is also evidence that brain metastases from melanoma can respond to BRAF/MEK inhibitor combination therapy. The nonrandomized phase II COMBI-MB trial demonstrated clinical benefit and acceptable toxicity for the combination of the BRAF inhibitor dabrafenib with the MEK inhibitor trametinib in 125 patients with brain metastases from *BRAF* V600-mutant melanoma.⁵¹⁴ Among the patients with asymptomatic brain metastases, an intracranial response was observed in 58% of those with untreated metastases and in 56% of those with previously treated metastases. In patients with symptomatic brain metastases, an intracranial response was observed in 59%. Use of the BRAF inhibitor vemurafenib for patients with both newly diagnosed and previously treated brain metastases from *BRAF* V600-mutant melanoma is supported by nonrandomized studies.^{515,516} Although there are no published prospective studies on the combination of vemurafenib and cobimetinib for patients with brain metastases from melanoma, there is high-quality evidence that, for distantly metastatic melanoma, combination therapy with vemurafenib and cobimetinib is associated with improved outcomes, compared with vemurafenib monotherapy.^{517,518} A case series showed that the BRAF/MEK inhibitor combination encorafenib/binimetinib showed good CNS penetration.⁵¹⁹ Prospective randomized trials are needed to determine which *BRAF*-directed therapy options provide the best results in patients with brain metastases from melanoma.

Lung Cancer

Systemic treatment options for patients with brain metastases from NSCLC include immunotherapy agents and targeted therapies for cancer that is anaplastic lymphoma kinase (ALK) rearrangement-positive and EGFR mutation-positive.

PD-1/PD-L1 Inhibitors

A phase II trial showed a 33% response rate for pembrolizumab in 18 patients with brain metastases from PD-L1-positive NSCLC.⁵¹² Pooled

analyses from a phase II trial⁵²⁰ and two phase III trials^{521,522} showed that nivolumab for patients with previously treated brain metastases from NSCLC is well-tolerated, though results from these analyses are currently only reported in abstract form.⁵²³ Nivolumab for patients with brain metastases from NSCLC is also supported by results from a retrospective multi-institutional study.⁵²⁴

ALK Inhibitors

At time of diagnosis, brain metastases are present in 24% of patients with ALK rearrangement-positive NSCLC.⁵²⁵ In general, the panel prefers second- and third-generation ALK inhibitors for patients with brain metastases from ALK rearrangement-positive NSCLC, based on better activity profiles. Crizotinib inhibits *ALK* rearrangements, *ROS1* rearrangements, and some MET TKIs. Crizotinib does demonstrate some CNS activity,⁵²⁶ but the response and control rates appear to be clearly lower than newer generation ALK inhibitors.

In a randomized phase III trial, the ALK inhibitor alectinib was compared to crizotinib in 303 patients with advanced ALK rearrangement-positive NSCLC and no previous systemic therapy treatment.⁵²⁷ Brain metastases were reported in 40.3% of the sample. Among these patients, a CNS response was observed in 81% of patients in the alectinib arm (8 complete responses) and 50% of patients in the crizotinib arm (1 complete response). The median duration of intracranial response in these 122 patients was 17.3 months in the alectinib arm and 5.5 months in the crizotinib arm. Pooled analyses from two phase II studies^{528,529} including patients with ALK rearrangement-positive NSCLC that progressed on crizotinib showed that alectinib was associated with a good objective response rate and excellent disease control in patients with brain metastases.⁵³⁰ Patients who did not receive previous brain RT seemed to have a better response to alectinib than patients with previous RT, but the sample size for these analyses was small.

In a similar randomized phase III trial, brigatinib, another ALK inhibitor, was compared to crizotinib in 275 patients with locally advanced or metastatic ALK rearrangement-positive NSCLC and no previous systemic therapy treatment.⁵³¹ Among patients with brain metastases ($n = 90$), an intracranial response was more likely in the brigatinib arm than in the crizotinib arm (67% vs. 17%, respectively; OR, 13.00; 95% CI, 4.38–38.61). Complete intracranial responses were observed in 16 patients who received brigatinib and 2 patients who received crizotinib. Twelve-month survival without intracranial disease progression was greater in the brigatinib arm than in the crizotinib arm (67% vs. 21%, respectively; HR, 0.27; 95% CI, 0.13–0.54). Brigatinib treatment in patients with brain metastases from ALK rearrangement-positive NSCLC and disease progression on crizotinib is supported by the phase II ALTA trial, which showed an intracranial response rate of 67%.⁵³² Median intracranial PFS was 12.8 months in these patients. A dosing schedule of 180 mg once daily with a 7-day lead-in at 90 mg was used to reduce the chance of early-onset moderate to severe pulmonary adverse events.

The ALK inhibitor ceritinib was evaluated in a phase I trial including 246 patients with ALK rearrangement-positive NSCLC.⁵³³ About half the sample had brain metastases ($n = 124$). Retrospective analyses were used to evaluate intracranial response in these patients. Disease control rate was 78.9% in patients not previously treated with an ALK inhibitor and 65.3% in patients with previous ALK inhibitor treatment. However, most of these patients had received RT to the brain. Therefore, based on this study, it is difficult to draw conclusions regarding the contribution of RT versus ceritinib to disease control rates in these patients. In the nonrandomized phase II ASCEND-7 trial, out of 97 patients with measurable brain metastasis from ALK-positive NSCLC, the intracranial ORR for ceritinib was 39.2%.⁵³⁴ Intracranial ORR was higher in patients who were ALK-naïve, compared to those previously treated with an ALK inhibitor (47.5% vs 33.3%, respectively).

A phase II trial in which the third-generation ALK/ROS1 TKI lorlatinib was evaluated in patients with ALK-positive NSCLC previously treated with an ALK TKI showed that this agent may be active against CNS metastases.⁵³⁵ Post hoc efficacy analyses from the randomized phase III CROWN trial in which patients with advanced or metastatic ALK-positive NSCLC were randomized to receive lorlatinib or crizotinib showed that, in 78 patients with brain metastases at baseline, complete CNS response was observed in 61% of patients who received lorlatinib, compared to 15% in those who received crizotinib.⁵³⁶ Among the complete responses in the lorlatinib arm, median duration of response was not reached.

Epidermal Growth Factor Receptor Tyrosine Kinase Inhibitors

Some treatment options for patients with advanced NSCLC that harbor EGFR-TKI-sensitizing mutations have been evaluated and are now available.

Older-generation EGFR-TKIs have demonstrated some CNS activity. Gefitinib for treatment of patients with CNS metastases from NSCLC is supported by phase II studies.^{537,538} Pulsatile erlotinib is supported by a phase I study including patients with untreated CNS metastases from EGFR-sensitizing mutation-positive NSCLC.⁵³⁹ Afatinib treatment was evaluated in patients with CNS metastasis from NSCLC and with disease progression following platinum-based chemotherapy and either erlotinib or gefitinib ($n = 100$).⁵⁴⁰ Cerebral response was observed in 35% of these patients, and disease control was observed in 66%.

In a randomized phase III FLAURA trial, the EGFR-TKI osimertinib was compared to a different EGFR-TKI (gefitinib or erlotinib) in 556 patients with previously untreated EGFR-sensitizing mutation-positive NSCLC.⁵⁴¹ CNS metastases were reported in 20.9% of the sample. Median PFS was greater for these patients in the osimertinib arm than in the standard EGFR-TKI arm (15.2 months vs. 9.6 months, respectively; HR, 0.47; 95% CI, 0.30–0.74; $P < .001$). Preplanned exploratory analyses including 41

patients with at least one measurable CNS lesion showed a CNS ORR of 91% in the osimertinib arm, compared to 68% in the EGFR-TKI arm, but this difference did not reach statistical significance (OR, 4.6; 95% CI, 0.9–34.9; $P = .066$).⁵⁴² Twenty-three percent of patients in the osimertinib arm had a complete CNS response, compared to none of the patients in the EGFR-TKI arm. CNS disease control rate did not significantly differ between the study arms in patients with at least one measurable CNS lesion.

Osimertinib has also been evaluated in the randomized phase III AURA3 trial, in which it was compared to pemetrexed with platinum-based therapy in 419 patients with *T790M* mutation-positive advanced NSCLC that progressed after first-line EGFR-TKI therapy.⁵⁴³ CNS metastases were reported in 34.4% of the sample. Median PFS was greater for these patients in the osimertinib arm than in the pemetrexed/platinum arm (8.5 months vs. 4.2 months, respectively; HR, 0.32; 95% CI, 0.21–0.49). Preplanned analyses including 46 patients with at least one measurable CNS lesion showed a significantly greater CNS ORR for the osimertinib arm than in the pemetrexed/platinum arm (70% vs. 31%, respectively; OR, 5.13; 95% CI, 1.44–20.64; $P = .015$).⁵⁴⁴ CNS disease control rate was 93% in the osimertinib arm, compared to 63% in the pemetrexed/platinum arm. Median CNS duration of response was also longer in the patients who received osimertinib.

Results from the nonrandomized phase II T790M cohort of the Japanese OCEAN study showed an ORR of 66.7% among 39 patients previously untreated with RT.⁵⁴⁵ Pooled analyses from two phase II studies^{546,547} including patients with *T790M*-positive advanced NSCLC that progressed following treatment with EGFR-TKI therapy showed a CNS ORR of 54% and disease control rate of 92%.⁵⁴⁸ Median CNS duration of response and median PFS were not reached.

MET Inhibitors

MET exon 14 skipping mutations are present in 3% to 4% of patients with NSCLC.⁵⁴⁹⁻⁵⁵¹ A phase 2 study of the MET inhibitor capmatinib showed a 53.8% intracranial response rate in 13 patients with NSCLC with a MET exon14 skipping mutation and brain metastases.⁵⁵²

RET Inhibitors

RET fusions are found in 1% to 2% of patients with NSCLC.^{553,554} In the phase I/II LIBRETTO-001 trial, treatment with the RET inhibitor selpercatinib was evaluated in 80 patients with brain metastases.⁵⁵⁵ Intracranial PFS was 13.7 months. An intracranial ORR of 82% in 22 patients with measurable CNS-involved disease at baseline was observed, with complete responses in 23%. Among 38 intracranial responders, median duration of intracranial response was not reached.

Other Systemic Therapy Options

A phase I/II study of topotecan plus WBRT has shown a 72% response rate in 75 patients with brain metastases.⁵⁵⁶ Unfortunately, a follow-up phase III trial including only patients with brain metastases from lung cancer was closed early due to slow accrual.⁵⁵⁷

Breast Cancer

Capecitabine combined with a number of agents has been evaluated in patients with brain metastases from HER2-positive breast cancer. Capecitabine combined with the TKI lapatinib for patients with brain metastases from HER2-positive breast cancer is supported by a systematic review and pooled analysis showing an ORR of 29.2%, a disease control rate of 65.1%, and a 2-year OS rate of 33.4%.⁵⁵⁸

In the HER2CLIMB phase III trial, patients with HER2-positive metastatic breast cancer who were previously treated with HER2-directed therapy (N = 612) were randomized to receive trastuzumab and capecitabine combined with either the TKI tucatinib or a placebo.⁵⁵⁹ Among the patients with brain metastases at baseline (47.5% of the sample), both PFS (HR,

0.46; 95% CI, 0.31–0.67) and OS (HR, 0.58; 95% CI, 0.40–0.85) were superior in the tucatinib arm. The estimated 1-year PFS was 24.9% for these patients who received tucatinib, compared to 0% in patients who received the placebo, with duration of PFS being 7.6 months and 5.4 months, respectively. Exploratory analyses of 291 patients with brain metastases showed that both CNS PFS (HR, 0.36; 95% CI, 0.22–0.57; $P < .00001$) and OS (HR, 0.49; 95% CI, 0.30–0.80; $P = .004$) were significantly greater in patients who received tucatinib, compared to patients who received the placebo.⁵⁶⁰ Based on study results, the FDA approved tucatinib in combination with trastuzumab and capecitabine in 2020 for patients with advanced unresectable or metastatic HER2-positive breast cancer (including patients with brain metastases) who were previously treated with HER2-directed therapy.

A phase II study supports use of capecitabine combined with the TKI neratinib in patients with CNS metastases from HER2-positive breast cancer.⁵⁶¹ CNS metastases in most of the patients were previously treated with surgery or RT. Results from this study helped inform development of the phase III NALA trial, in which patients with HER2-positive metastatic breast cancer who received at least 2 lines of HER2-directed therapy were randomized to receive capecitabine and neratinib or capecitabine and lapatinib (N = 621).⁵⁶² Patients in the capecitabine/neratinib arm had superior PFS compared to those in the capecitabine/lapatinib arm (HR, 0.76; 95% CI, 0.63–0.93; $P = .006$), though there was no OS advantage. Further, patients who received capecitabine/neratinib were less likely to have required intervention for symptomatic CNS metastases than patients in the capecitabine/lapatinib arm (22.8% vs. 29.2%, respectively; $P = .043$). Subgroup analyses of 101 patients who had known CNS metastases at baseline showed that mean PFS through 24 months was greater in the capecitabine/neratinib arm (7.8 months) than in the capecitabine/lapatinib arm (5.5 months), but this result did not reach statistical significance (HR, 0.66; 95% CI, 0.41–1.05; $P = .074$).⁵⁶³ Among

patients with at least one target CNS lesion (n = 32), intracranial ORR was 26.3% in the capecitabine/neratinib arm and 15.4% in the capecitabine/lapatinib arm. In a randomized phase II trial evaluating paclitaxel combined with neratinib, compared to trastuzumab combined with paclitaxel, in patients with untreated metastatic HER2-positive breast cancer, incidence of symptomatic or progressive CNS events were significantly lower in the neratinib arm (8.3% vs. 17.3%, respectively; HR, 0.48; 95% CI, 0.29–0.79; $P = .002$).⁵⁶⁴ Though patients with asymptomatic CNS metastases at baseline were eligible to participate in this trial, they comprised only 3.8% of the study sample, limiting the conclusions that can be drawn about the efficacy of this regimen for these patients.

Trastuzumab, a large monoclonal antibody, is used for treatment of HER2-positive breast cancer, but it does not penetrate the BBB. Therefore, there are concerns about risk of breast cancer metastasizing to the brain for patients treated with normal-dose trastuzumab.⁵⁶⁵ Results of the primary efficacy analysis from the phase 2 PATRICIA study including 39 patients with metastatic HER2-positive breast cancer and CNS progression (previously treated with RT) showed an intracranial ORR of 11% with median duration of response of 4.6 months for high-dose trastuzumab with pertuzumab.⁵⁶⁶

Two HER2-targeting antibody-drug conjugates have been evaluated for treatment of brain metastases from HER2-positive breast cancer. A study describing exploratory analyses from the nonrandomized phase IIIb KAMILLA study showed that the antibody-drug conjugate ado-trastuzumab emtansine, which contains the cytotoxic agent DM1, was associated with a 21.4% ORR (mostly partial responses) in 126 patients with measurable CNS metastases.⁵⁶⁷ CNS tumors significantly diminished in size in 50% (95% CI, 18.7%–81.3%). Subgroup analysis from the ongoing open-label phase II DESTINY-Breast01 trial showed that the antibody-drug conjugate fam-trastuzumab deruxtecan-nxki (deruxtecan being a DNA

topoisomerase 1 inhibitor) was associated with a 58% ORR in 24 patients with asymptomatic brain metastases from HER2-positive breast cancer who were previously treated with ado-trastuzumab emtansine.⁵⁶⁸ Partial intracranial responses were observed in 41%. In the multicenter open-label randomized phase III DESTINY-Breast03 trial, in which fam-trastuzumab deruxtecan-nxki is being compared to ado-trastuzumab emtansine in patients with metastatic HER2-positive breast cancer previously treated with trastuzumab and a taxane, results presented at an annual meeting showed that median PFS was significantly greater in the fam-trastuzumab deruxtecan-nxki arm, compared to the ado-trastuzumab emtansine arm (15.0 months vs. 5.7 months, respectively; HR, 0.38; 95% CI, 0.23–0.64).⁵⁶⁹

Capecitabine monotherapy treatment in patients with brain metastases from breast cancer is supported by a phase I trial⁵⁷⁰ and case reports.⁵⁷¹⁻⁵⁷⁴ A study of high-dose methotrexate in patients mostly with breast cancer achieved disease control in 56% of patients.⁵⁷⁵ The use of cisplatin and etoposide monotherapies and combination therapy in patients with brain metastases from breast cancer is supported by nonrandomized studies published in the 1990s.⁵⁷⁶⁻⁵⁷⁸

NCCN Recommendations

Workup

Brain MRI with and without contrast is recommended for diagnosis, visualization, and monitoring in patients with brain metastases. Patients who present with a single mass or multiple lesions on MRI or CT imaging suggestive of metastatic cancer to the brain, and who do not have a known primary, require a careful systemic workup with chest x-ray or CT with contrast, abdominal or pelvic CT with contrast, or other tests as indicated. Whole-body PET/CT may be considered. If no other readily accessible tumor is available for biopsy, a stereotactic or open biopsy resection is indicated to establish a diagnosis.

Treatment for Limited Metastatic Lesions

The panel defines “limited” brain metastases as patients for whom SRS represents an effective alternative to WBRT, but with more cognitive protection.⁴⁶⁷ Because brain metastases are often managed by physicians from multiple disciplines, the NCCN Panel encourages multidisciplinary consultation prior to treatment for optimal planning.

Surgical resection may be considered in select cases (eg, for management of mass effect or other symptoms; for tumors >3 cm that are surgically accessible; if there is no other readily accessible tumor to be biopsied). For patients with newly diagnosed or stable systemic disease, treatment options include SRS (preferred) and WBRT (HA-WBRT with memantine, if eligible). Patients eligible for HA-WBRT with memantine include those with a life expectancy of at least 4 months and brain metastases not within 5 mm of the hippocampi. When patients are managed with SRS, NCCN does not recommend the routine addition of WBRT, as this approach has been consistently associated with cognitive deterioration and no difference in survival,⁴⁶⁴ but the addition of SRS boost in very select patients (ie, large lesions or radioresistant histology) already receiving WBRT may be considered for the purpose of local disease control.⁴⁹⁶ The management of patients with disseminated systemic disease or poor prognosis should be individualized and may include strategies of best supportive care, WBRT (HA-WBRT with memantine, if eligible), SRS, or a trial of CNS-active systemic agents; multidisciplinary evaluation is encouraged.

In patients with systemic cancers with options for CNS-active systemic therapies (eg, *ALK* or *EGFR* mutations in NSCLC; *BRAF* mutations in metastatic melanoma, HER2-positive breast cancer), upfront systemic therapy alone may be considered in carefully selected, asymptomatic patients. When considering a trial of upfront systemic therapy alone for brain metastases, NCCN recommends a multidisciplinary discussion

between medical and radiation oncologists and ongoing CNS surveillance with brain MRIs to allow for early interventions in cases of progression or inadequate response.

Patients should be followed with brain MRI every 2 to 3 months for 1 to 2 years and then every 4 to 6 months indefinitely. Closer follow-up every 2 months may be particularly helpful for patients treated with SRS or systemic therapy alone.⁴⁶⁵ Following SRS, imaging changes may reflect treatment changes or tumor progression. Advanced MRI, multidisciplinary review, or observation with early repeat imaging may be considered. Tumor sampling may be considered if recurrence versus treatment effect remains unclear. Upon detection of recurrent disease, prior therapy clearly influences the choice of further therapies. Patients with recurrent CNS disease should be assessed for local versus systemic disease, because the optimal therapy may differ. For local recurrences, patients who were previously treated with surgery only can receive the following options: 1) surgery with consideration of SRS or RT to the surgical bed; 2) single-dose or fractionated SRS; 3) WBRT (HA-WBRT with memantine, if eligible); or 4) systemic therapy. However, patients who previously received WBRT generally should not undergo WBRT at recurrence due to concern regarding neurotoxicity. If the patient had previous SRS with a durable response for greater than 6 months, reconsider SRS if imaging or biopsy supports active tumor and not necrosis. Repeat SRS to a prior location is a category 2B recommendation.

If isolated CNS disease progression occurs in the setting of limited systemic treatment options and poor PS, management of brain metastases should be individualized and may include best supportive care, WBRT (HA-WBRT with memantine, if eligible), SRS, and CNS-active systemic agents. WBRT re-irradiation is generally discouraged due to toxicity to cognition and quality of life and should be administered only in highly selected circumstances. Laser thermal ablation is an option for

patients with relapsed brain metastases or refractory radiation necrosis who are not considered surgical candidates. This procedure should only be carried out at an experienced academic center.

Treatment for Extensive Metastatic Lesions

Patients diagnosed with extensive metastatic lesions should generally be treated with WBRT (HA-WBRT with memantine, if eligible) or SRS as primary therapy. For WBRT dosing, the standard dosing is 30 Gy in 10 fractions, with limited evidence to support prolonged fractionation schemes beyond 10 fractions. For patients with poor neurologic performance, a more rapid course of RT can be considered (20 Gy, delivered in 5 fractions). SRS may be considered in select patients, particularly those with good PS and low overall tumor volume. Some patients may be eligible for upfront systemic therapy treatment. Palliative neurosurgery may also be considered if a lesion is causing a life-threatening mass effect, hemorrhage, or hydrocephalus.

After WBRT or SRS, patients should have a repeat contrast-enhanced brain MRI scan every 2 to 3 months for 1 to 2 years, then every 4 to 6 months indefinitely. Some patients will need brain MRIs every 2 to 3 months indefinitely based on the frequency of detecting new metastases. Treatment for recurrences are individualized and may include best supportive care, surgery, WBRT (HA-WBRT with memantine, if eligible), SRS, or a trial of CNS-active systemic therapy; multidisciplinary review is recommended. Repeat WBRT is generally discouraged due to toxicity to cognition and quality of life and should only be administered in highly selected circumstances.

Leptomeningeal Metastases

Leptomeningeal metastasis or neoplastic meningitis refers to malignant cells' multifocal seeding of the leptomeninges. It is known as leptomeningeal carcinomatosis or carcinomatous meningitis when these

cells originate from a solid tumor. When it is related to systemic lymphoma, it is called lymphomatous meningitis, and when associated with leukemia, it is termed leukemic meningitis. Leptomeningeal metastasis occurs in approximately 5% of patients with cancer.⁵⁷⁹ This disorder is being diagnosed with increasing frequency as patients with cancer live longer with improved systemic therapeutics and as neuroimaging studies improve. Most cases arise from breast cancers, lung cancers, and melanoma, which have the highest rate of leptomeningeal spread.^{580,581}

Tumor cells gain access to the leptomeninges by hematogenous dissemination, lymphatic spread, or direct extension. Once these cells reach the CSF, they are disseminated throughout the neuraxis by the constant flow of CSF. Infiltration of the leptomeninges by any malignancy is a serious complication that results in substantial morbidity and mortality. Common symptoms depend on location of involvement. When the posterior fossa is involved, patients can present with new cranial nerve palsies. Spinal cord-related symptoms can include pain (neck, back or radicular), focal motor or sensory dysfunction, and bowel/bladder dysfunction. Common signs of involvement of the ventricular system include headache, nausea/vomiting, and confusion. The median survival of patients diagnosed with this disorder is typically 2 to 4 months with death resulting from progressive neurologic dysfunction, but survival may be extended by early detection and intervention.^{580,581} Of note, the underlying tumor type can have some impact on OS.^{581,582}

Treatment Overview

Treatment goals in patients with leptomeningeal metastases are to improve or stabilize the patient's neurologic symptoms and to prolong survival.⁵⁸³ Unfortunately, there is a lack of standard treatments due to meager evidence in literature. Because treatment is largely palliative,

aggressive chemotherapy should only be given to patients most likely to benefit (see *Patient Stratification*).

Radiation Therapy

RT is mainly given for symptom alleviation, CSF flow correction, or debulking to facilitate systemic therapy.^{581,584-586} SRS may be an option for patients with focal leptomeningeal disease, particularly in the setting of focal disease causing CSF flow disruption.⁵⁸⁷

Surgery

The role of neurosurgery for leptomeningeal metastases is mainly limited to intraventricular catheter and subcutaneous reservoir placement for drug administration.⁵⁸⁸ This is preferred over lumbar punctures because of improved drug delivery, safety, superior pharmacokinetics, lower inter-patient variability, and patient comfort.⁵⁸⁹

Systemic Therapy

Some systemically administered agents can reach the leptomeninges, while others do not traverse the blood CSF barrier. Intrathecal chemotherapy can address non-bulky leptomeningeal disease, although it is essential to note that it is an effective treatment for brain parenchymal disease. Some drugs have good CNS penetration, particularly organ-specific targeted therapies or systemically administered chemotherapies given in high doses.⁵⁸³ Intrathecal therapy can involve either administration via a lumbar puncture or intraventricular injections via an Ommaya reservoir. However, both intra-CSF therapy and high-dose systemic therapy are associated with significant toxicity or complications and are therefore generally restricted to patients with good performance status.

Agents used for intra-CSF therapy are often histology-specific and, because they are directly injected into the CSF, have good drug bioavailability. The panel included intrathecal options deemed appropriate based on moderate benefit: methotrexate⁵⁹⁰⁻⁵⁹²; cytarabine^{591,593,594};

thiotepa^{592,595}; rituximab for lymphoma⁵⁹⁶; topotecan^{597,598}; etoposide⁵⁹⁹; and trastuzumab for HER2-positive breast cancer.⁶⁰⁰ Interferon alfa was removed as an intra-CSF chemotherapy option in 2020 due to discontinuation.

Breast cancers^{575,601} and lymphomas^{593,602} are also particularly responsive to high-dose methotrexate. In addition, osimertinib and weekly pulse erlotinib have been used for metastatic NSCLC with EGFR-sensitizing mutations [exon 19 deletion or exon 21 L858R mutation only for erlotinib (category 2B)].⁶⁰³⁻⁶⁰⁷

NCCN Recommendations

Patient Evaluation

Patients present with signs and symptoms ranging from injury to nerves that traverse the subarachnoid space, direct tumor invasion of the brain or spinal cord, alteration of the local blood supply, obstruction of normal CSF flow pathways leading to increased intracranial pressure, or interference with normal brain function. Patients should have a physical examination with a careful neurologic evaluation. MRI of the brain and spine should also be performed for accurate staging, particularly if the patient is a candidate for active treatment. A definitive diagnosis is most commonly made by CSF analysis via lumbar puncture if it is safe for the patient. The CSF protein is typically increased, and there may be a pleocytosis or decreased glucose levels and ultimately positive CSF cytology for tumor cells. Assessment of circulating tumor cells increases the sensitivity of tumor cell detection in CSF.⁶⁰⁸⁻⁶¹⁰ This assessment is now CLIA-approved in some states and should be done when it is available. CSF cytology testing has approximately 50% sensitivity with the first lumbar puncture, and up to 90% sensitivity after repeated CSF analyses in affected patients.^{585,586} Clinicians should be aware that lumbar punctures may be contraindicated in patients with anticoagulation, thrombocytopenia, or bulky intracranial disease. In these cases, suspicious CSF biochemical

results combined with suggestive clinical and/or radiologic features should be considered. Although a positive CSF cytology in patients with solid tumors is virtually always diagnostic, reactive lymphocytes from infections (for example, herpes zoster infection) can often be mistaken for malignant lymphocytes.

Patient Stratification

Once the diagnosis has been established, the patient's overall status should be carefully assessed to determine how aggressively the carcinomatous or lymphomatous meningitis should be treated.

Unfortunately, this disease is most common in patients with advanced, treatment-refractory systemic malignancies for whom treatment options are limited. In general, fixed neurologic deficits (such as cranial nerve palsies or paraplegia) do not resolve with therapy, although encephalopathies may improve dramatically. As a result, patients should be stratified into “poor-risk” and “good-risk” groups. The poor-risk group includes patients with KPS below 60; multiple, serious, major neurologic deficits; extensive systemic disease with few treatment options; bulky CNS disease; and neoplastic meningitis related to encephalopathy. The good-risk group includes patients with KPS greater than or equal to 60, no major neurologic deficits, minimal systemic disease, and reasonable systemic treatment options. Many patients fall between these two groups, and clinical judgment will dictate how aggressive their treatment should be.

Treatment

Patients in the poor-risk group are usually offered palliative/supportive care measures, though patients considered good-risk may also receive palliative/best supportive care if they do not desire further treatment. Fractionated EBRT to neurologically symptomatic sites (eg, to the whole brain for increased intracranial pressure or to the lumbosacral spine for a developing cauda equina syndrome) can be considered to temporarily improve function.

Chemotherapy (systemic or intrathecal) is recommended for patients considered good-risk. These patients may also receive SRS, WBRT, or involved-field RT to neurologically symptomatic or painful sites and to areas of bulky disease identified on neuroimaging studies. Craniospinal RT may also be considered, but only in highly select patients given the substantial toxicity and resultant bone marrow suppression that can limit future cancer-directed therapies.

CSF flow abnormalities are common in patients with neoplastic meningitis, and these often lead to increased intracranial pressure. Administering chemotherapy into the ventricle of a patient with a ventricular outlet obstruction increases the patient's risk for leukoencephalopathy. In addition, the agent administered may not reach the lumbar subarachnoid space where the original CSF cytology was positive if there are flow obstructions. Therefore, a CSF flow scan should be carried out if there are concerns about a CSF flow blockage (eg, a patient with hydrocephalus) before administration of intrathecal systemic therapy. If significant flow abnormalities are seen, fractionated EBRT can be administered to the sites of obstruction before repeating a CSF flow scan. High-dose systemically administered methotrexate remains an option for patients with breast cancer or lymphoma, as normal CSF flow is not required to reach cytotoxic concentrations.

The patient should be reassessed clinically and with a repeat CSF cytology. Cytology should be sampled from the lumbar spine, if possible, or via an intraventricular port. Neuraxis imaging with MRI is recommended if CSF cytology was initially negative or if there are new or worsening symptoms. Spine/brain MRI imaging can be considered for sites that were previously positive on a radiograph.

If negative cytology is achieved after induction, continue the induction chemotherapy for another month before switching to maintenance intrathecal chemotherapy. The CSF cytology status should be followed

every 4 to 8 weeks. If the patient is clinically stable or improving after induction and there is no clinical or radiologic evidence of progressive leptomeningeal disease, the patient should receive another 4 weeks of “induction” intrathecal chemotherapy or should consider switching intrathecal drugs for 4 weeks. This regimen should be followed by maintenance therapy and monthly cytology if the cytology has converted to negative or is improving (still positive) while the patient is clinically stable.

Progressive Disease

If the patient’s clinical status is deteriorating from progressive leptomeningeal disease or if the cytology is persistently positive, the clinician has several options: 1) RT to symptomatic sites; 2) systemic chemotherapy; or 3) palliative or best supportive care.

Metastatic Spinal Tumors

Bone metastases are a growing problem among patients with cancer due to increasing life expectancy, with the spine being the most frequently affected site. Spinal metastases primarily arise from breast, lung, prostate, and renal cancers.^{611,612} Extradural lesions account for about 95% of spinal tumors, mostly in the thoracic region.

Some patients are found to have vertebral involvement as an asymptomatic, incidental finding. However, for most affected patients, pain is the primary presenting symptom preceding neurologic dysfunction. Three types of pain have been classically defined. Local pain due to tumor growth is often described as a constant, deep aching that improves with steroid medications. Mechanical back pain varies with movement and position and is attributed to structural spinal instability. While seldom responsive to steroids, mechanical pain can be alleviated by surgical stabilization. Radicular pain is a sharp or stabbing sensation that occurs

when nerve roots are compressed by the tumor. Patients may experience any one or a combination of these types of pain.

Spinal cord compression is the most debilitating complication of spine metastases. It affects 5% to 10% of all patients with cancer, with more than 20,000 cases diagnosed each year in the United States.⁶¹³ The majority of patients initially complain of progressive radicular pain.⁶¹⁴ This is followed by neurologic symptoms such as motor weakness and sensory loss, and may even include autonomic bladder dysfunction. If left untreated, neurologic deficits rapidly progress to paralysis. Unfortunately, a study of 319 patients with cord compression revealed significant delay in the report of initial pain (3 months) as well as diagnosis (2 months) that can lead to irreversible spinal cord damage.⁶¹⁵ Therefore, it is paramount that the clinician watches for early suspicious signs and establishes prompt diagnosis by spine MRI. Once diagnosed, spinal cord compression is considered a medical emergency; intervention should be implemented immediately to prevent further neurologic decline.

Treatment Overview

Dissemination to the spinal column is largely incurable. Therefore, the goals of treatment are palliation and improvement of quality of life through preservation of neurologic function, pain relief, and stabilization of mechanical structure. Exceptions include patients with oligometastases for which surgery or other ablative treatments such as stereotactic radiation may achieve prolonged disease control and, in rare cases, possible cure.⁶¹⁶ Patients with spine metastases require care from a multidisciplinary team, including neurosurgeons; orthopedic surgeons; radiologists and interventional radiologists; and specialists in pain management; care of the bowel, bladder, and back; and ambulatory support.

The type and aggressiveness of the primary tumor often dictates the choice of treatment, as different cancers have varying sensitivities to systemic therapy and RT. In addition, patient characteristics including PS and comorbidities will determine whether they can tolerate surgery and, if so, which surgical technique should be used.

Surgery

There is general consensus that a patient should have a life expectancy of at least 3 months to be a surgical candidate. Paraplegia for over 24 hours is a strong relative contraindication due to low chances of improvement when prolonged neurologic deficits exist before surgery.⁶¹⁷ Patients with hematologic malignancies should also be excluded, as they are best managed by RT or systemic therapy. Because estimation of life expectancy can be difficult, several groups have developed prognostic scoring systems to help predict surgical outcomes.⁶¹⁸⁻⁶²¹

Modern surgical techniques enable surgeons to achieve 360° decompression of the spinal cord, and stabilization can be performed concomitantly, if required. The development of a plethora of spinal implants composed of high-quality materials such as titanium greatly improves reconstruction outcome. The surgical approach— anterior, posterior, or combined/circumferential—is primarily determined by disease anatomy.^{622,623}

Sundaresan and colleagues⁶¹⁶ reported favorable results using a variety of surgical approaches on 80 patients with solitary spine metastases. Both pain and mobility were improved in the majority of patients. OS reached 30 months, with 18% of patients surviving 5 years or more. The best outcome was observed in patients with kidney and breast cancers.

Surgery followed by adjuvant EBRT has emerged as a highly effective approach in relieving spinal cord compression and restoring function, especially for solid tumors. A meta-analysis including 24 surgery cohort

studies and four RT studies found that patients are twice as likely to regain ambulatory function after surgery than RT alone.⁶²⁴ However, data also revealed significant surgery-related mortality (6.3%) and morbidity (23%). In another review of literature from 1964 to 2005, anterior decompression with stabilization plus RT was associated with superior outcome over RT alone or laminectomy, achieving 75% mean improvement in neurologic function. However, high surgical mortality rate (mean 10%) was also reported.⁶²⁵

To date, only one relevant randomized trial has been reported.⁶²⁶ Approximately 100 patients with metastatic spinal compression were randomized to surgery plus postoperative RT or RT alone. Compared to the RT group, significantly more patients in the surgery group regained walking ability (84% vs. 57%; $P = .001$) and for a longer period of time (median 122 days vs. 13 days; $P = .003$). The impressive results were obtained with strict eligibility criteria. The study excluded patients with radiosensitive tumors, neurologic deficits for 24 hours, multiple spinal tumors, lesions only compressing spinal roots, and prior RT to the vertebrae. Although studies demonstrated high efficacy of surgery, the formidable complications related to surgery cannot be overlooked. Using the Nationwide Inpatient Sample all-payer database, Patil et al⁶²⁷ reviewed data of more than 26,000 patients who had undergone surgery for spinal metastases. The in-hospital mortality and complication rates were 5.6% and 22%, respectively. The most common complications were pulmonary (6.7%) and hemorrhages or hematomas (5.9%). Clearly, careful individual patient selection based on life expectancy and overall health is warranted.

Radiation Therapy

Traditionally, EBRT has been the main form of treatment for spinal metastases. In the modern surgery era, RT alone is often not sufficient in achieving decompression or stabilization (see above), but it is routinely used as adjuvant therapy following surgery as it is difficult to obtain wide

negative margins. Given the potential impact of RT on wound healing, most studies posed an interval of 1 to 3 weeks between resection and subsequent RT.⁶²⁸

In general, solid tumors are considered either moderately radiosensitive (eg, breast and prostate cancers) or radioresistant (eg, melanoma; osteosarcomas; cancers of the thyroid, colon, and kidney).⁶²⁹ On the other hand, hematologic malignancies such as lymphomas and multiple myelomas are highly responsive to RT and systemic therapy. Hence, RT alone is often utilized as therapy for these cancers, even in the presence of cord compression. An excellent response to RT alone for spinal cord compression was reported by Marazano and colleagues.⁶³⁰ Three hundred patients with predominately solid tumor histologies were randomized to a short-course (8 Gy x 2 days) or split-course (5 Gy x 3 days; 3 Gy x 5 days) schedule. After RT, 35% of nonambulatory patients regained walking ability, and pain relief was recorded in 57% of patients with a median survival of 4 months. Efficacy of RT was highly dependent on the histology: 70% of patients with nonambulatory breast cancer recovered mobility compared to only 20% of hepatocellular carcinoma patients. A randomized controlled trial including 342 patients with metastatic cancer (solid tumor) and spinal cord or cauda equina compression showed that single-fraction dosing (ie, 8 Gy in 1 fraction) did not meet criteria for noninferiority for ambulatory status at 8 weeks (compared to 20 Gy in 5 fractions).⁶³¹

Where there is no compression, fracture, or instability, EBRT is effective in achieving local control as a primary treatment. A systematic review of seven retrospective studies including 885 patients reported a mean local control rate of 77% with EBRT.⁶²⁹ RT is also a mainstay of palliative treatment for patients with poor PS, significant comorbidities, and/or limited life expectancy (<3–4 months). Klimo's meta-analysis, including 543 patients treated by RT, revealed pain control rates of 54% to 83%.⁶²⁴

Unlike surgery, RT has no immediate significant treatment-related complications and very few local recurrences. However, it increases surgical complications as it impairs wound healing.

Stereotactic radiation approaches (SRS or stereotactic body RT [SBRT]) allow precise high-dose targeting in one or two fractions while minimizing exposure of the nearby spinal cord and other organs at risk.⁶³² This is especially important in pre-irradiated patients. Consensus guidelines should be followed for stereotactic radiation planning and delivery.⁶³²⁻⁶³⁴ Reasonable dosing schedules for the postoperative setting have been published by Redmond et al.⁶³⁴

A review including 59 publications with 5655 patients who received SRS for spinal metastases showed 1-year local control rates of 80% to 90% for newly diagnosed disease, 80% following surgery, and 65% for previously irradiated disease.⁶³⁵ Results of the phase II/III RTOG 0631 trial demonstrated the feasibility of SRS for these patients.⁶³⁶ The phase III component of this trial comparing single-dose stereotactic RT of 16 or 18 Gy to single-dose EBRT of 8 Gy in patients with one to three spinal metastases found no differences in the primary endpoint of pain response at 3 months.⁶³⁷ However, improvements in pain responses were observed in an open-label randomized multicenter phase II/III trial in which SRS (24 Gy in 2 fractions) was compared to EBRT (20 Gy in 5 fractions) in 229 patients with painful spine metastases.⁶³⁸ Intent-to-treat analyses showed that complete response to pain was significantly greater in the SRS arm than in the EBRT arm (35% vs. 14%, respectively; RR, 1.33; 95% CI, 1.14–1.55; $P = .0003$).

In addition to the goal of pain improvement, stereotactic radiation can also be used as a strategy to improve disease control and survival outcomes in patients with oligometastatic disease. For example, in the open-label randomized phase II SABR-COMET trial, standard palliative RT was compared to stereotactic ablative radiotherapy (SABR) in 99 patients with

1 to 5 metastatic lesions and a controlled primary tumor.⁶³⁹ Five-year OS was significantly greater in the SABR arm than in the palliative RT arm (42.3% vs. 17.7%; $P = .006$).

Vertebral Augmentation

Percutaneous vertebroplasty and kyphoplasty involve injection of cement (polymethyl methacrylate) into the vertebral body. Vertebroplasty is a direct injection, while kyphoplasty involves inserting a balloon that provides a cavity for the injection. These vertebral augmentation procedures immediately reinforce and stabilize the column, thereby relieving pain and preventing further fractures.⁶⁴⁰ They are suitable in poor surgical candidates with painful fractures, but are relatively contraindicated in the case of spinal cord compression because they do not achieve decompression. Symptomatic complications occur in up to 8% of patients (mostly with vertebroplasty), including embolization of the cement and local metastasis along the needle tract.

Percutaneous radiofrequency ablation (RFA) can also be considered for the treatment of spinal metastases to promote pain improvement and disease control. In a multicenter prospective trial including 50 patients with painful vertebral body metastases, RFA in the thoracic/lumbar region with cement augmentation was associated with improved pain and health-related quality of life.⁶⁴¹

Systemic Therapy

Corticosteroids remain a routine initial prescription for patients presenting with cord compression, with a number of theoretical benefits including anti-inflammation, reduction in edema, short-term neurologic function improvement, and enhanced blood flow. However, the preference between high-dose dexamethasone (96 mg daily) and low-dose (10–16 mg daily) is still unclear.⁶⁴²⁻⁶⁴⁴

Systemic therapy has a limited role in metastatic spinal tumors except for chemosensitive tumors such as lymphoma, myeloma, small cell lung cancer, and germ cell tumors. Agents efficacious for the primary tumor are used.

NCCN Recommendations

Workup

Initial workup depends on the presence or absence of symptoms. Patients with an incidental, asymptomatic, metastatic lesion confirmed by systemic imaging can be observed with MRI. However, biopsy and further treatment of an incidental lesion are indicated if treatment of the patient is altered as a result of treatment of the incidental lesion. In the absence of symptoms, it is not mandatory to obtain a spinal MRI for every incidental metastatic lesion seen on surveillance bone scans. The alternate category involves severe or new back pain. Increasing intensity, duration, and changes in the character of pain should trigger an evaluation with an MRI study, even in patients with pre-existing degenerative spine conditions. Immediate spinal MRI is warranted in the occurrence of neurologic symptoms, including weakness, paresthesias, and bladder or bowel incontinence. Contrast can be used to highlight and further evaluate any focal abnormality. The MRI can be used to image the entire spine or a focal area of interest. If the patient is unable to have an MRI, then a CT myelogram is recommended.

A normal neurologic examination implies that there is no spinal radiculopathy or myelopathy correlating with the patient's symptoms. In this case, other causes should be considered (eg, leptomeningeal disease). An abnormal neurologic examination includes motor abnormalities, sphincter abnormalities, and/or sensory deficits attributable to a dysfunction of nerve root(s) and/or the spinal cord. Therefore, detection of radiculopathy, myelopathy, or cauda equina syndrome is indicative of an abnormal examination. However, reflex asymmetry and/or

presence of pathologic reflexes, as well as sensory deficits of a stocking/glove distribution are excluded. Spinal instability may be evaluated using the Spine Instability Neoplastic Score.⁶⁴⁵

Treatment

Once metastatic vertebral involvement is diagnosed, treatment is based on whether the patient is suffering from spinal cord compression, fracture, or spinal instability. In the presence of multiple metastatic spinal tumors, the one causing the patient's main symptoms is addressed first. Additional tumors can be treated at a later point according to the algorithm.

Radiographic spinal cord compression implies deformation of the spinal cord because of epidural tumor, retropulsed bone fragment, or both. It should be noted that epidural tumor may occupy part of the spinal canal with or without partial obliteration of CSF around the spinal cord. Those cases are excluded because there is no cord deformation. For tumors occurring below L1, any canal compression of 50% or more should be considered of equal importance as spinal cord compression. Patients with radiographic cord compression should start on dexamethasone (10–100 mg) to alleviate symptoms. Decompressive surgery (concomitant stabilization if indicated) and adjuvant RT is the preferred treatment (category 1) where there is spinal instability and no surgical contraindication. Primary EBRT alone is appropriate for patients with radiosensitive cancers (hematologic malignancies) and without evidence of spinal instability. Many fractionation schemes are available (8 Gy in 1 fraction, 20 Gy in 5 fractions, or 30 Gy in 10 fractions); the most common is a total of 30 Gy in 3-Gy daily fractions for 10 days.^{646,647} Tolerance at the spinal cord and/or nerve route must be considered in determining dose. Primary systemic therapy is also an option for chemo-responsive tumors in the absence of clinical myelopathy, with close neurologic monitoring. In general, a treatment interval of at least 6 months is recommended.

Metastases to the spine without cord compression include the presence of tumor in the vertebral body, pedicle(s), lamina, transverse, or spinous process. It can also include epidural disease without cord deformation. Patients in this category should be assessed for fractures and spinal instability. Because the criteria for spinal destabilization secondary to tumor remain unclear, consultation by a surgeon is recommended. *Spinal instability* is grossly defined as the presence of significant kyphosis or subluxation (deformity) or of significantly retropulsed bone fragment. Not every pathologic fracture implies unstable structure. The degree of kyphosis or subluxation compatible with instability depends on the location of the tumor in the spine. The cross-sectional area of the vertebral body unaffected by the tumor and the patient's bone mineral density are additional factors affecting stability. In addition, vertebral body involvement is more important than dorsal element involvement with regard to stability. Circumferential disease as well as junctional and contiguous tumor location should be taken into account when assessing spinal stability. If fracture or instability is detected, the patient should undergo surgical stabilization or minimally invasive vertebral augmentation to relieve pain. These procedures should be followed by adjuvant RT to obtain local control.

If no fracture or instability is found, EBRT is the treatment of choice. Stereotactic RT is a preferred option for oligometastatic lesions and may also be appropriate for radioresistant histologies. Other alternatives are systemic therapy for responsive tumors, or surgery plus adjuvant RT in select cases. Patients experiencing intractable pain or rapid neurologic decline during RT should be considered for surgery. Neurologic deterioration is apparent when the patient's neurologic examination is becoming worse on a daily basis and the patient's ambulatory status is threatened. Intractable pain means that pain is not controlled with oral analgesics or that the patient cannot tolerate the medication due to side effects.

Progression and Recurrence

Follow-up involves MRI or CT imaging within 1 to 3 months post-treatment, then every 3 to 4 months for 1 year, then as clinically indicated.

Upon detection of progression or recurrence on imaging scans, management strategy is based on previous treatment. Patients who underwent prior RT or surgery plus adjuvant RT may consider surgery or re-irradiation to the recurred area. Stereotactic RT may be appropriate for select patients. Clinicians should plan 6 months or more between treatments in consideration of tolerance of the spine and its nerve roots. Retreatment dose should be limited to no more than 10 Gy to the surface of the spinal cord. Radioablation/augmentation may be used as clinically indicated for painful lesions. In patients who were previously treated with systemic therapy, surgery may be indicated depending upon the degree of spinal stability/cord compression. RT may also be considered.
